The Stability of Cognitive Abilities: A Meta-Analytic Review of Longitudinal Studies

Moritz Breit[1], Vsevolod Scherrer[1], Elliot M. Tucker-Drob[2], and Franzis Preckel[1]

[1] Department of Psychology, University of Trier

[2] Department of Psychology, The University of Texas at Austin

Cognitive abilities, including general intelligence and domain-specific abilities such as fluid reasoning, comprehension knowledge, working memory capacity, and processing speed, are regarded as some of the most stable psychological traits, yet there exist no large-scale systematic efforts to document the specific patterns by which their rank-order stability changes over age and time interval, or how their stability differs across abilities, tests, and populations. Determining the conditions under which cognitive abilities exhibit high or low degrees of stability is critical not just to theory development but to applied contexts in which cognitive assessments guide decisions regarding treatment and intervention decisions with lasting consequences for individuals. In order to supplement this important area of research, we present a meta-analysis of longitudinal studies investigating the stability of cognitive abilities. The meta-analysis relied on data from 205 longitudinal studies that involved a total of 87,408 participants, resulting in 1,288 test–retest correlation coefficients among manifest variables. For an age of 20 years and a test–retest interval of 5 years, we found a mean rank-order stability of $\rho = .76$. The effect of mean sample age on stability was best described by a negative exponential function, with low stability in preschool children, rapid increases in stability in childhood, and consistently high stability from late adolescence to late adulthood. This same functional form continued to best describe age trends in stability after adjusting for test reliability. Stability declined with increasing test–retest interval. This decrease flattened out from an interval of approximately 5 years onward. According to the age and interval moderation models, minimum stability sufficient for individual-level diagnostic decisions ($r_{tt} = .80$) can only be expected over the age of 7 and for short time intervals in children. In adults, stability levels meeting this criterion are obtained for over 5 years.

Public Significance Statement

This meta-analytic review finds that cognitive abilities are highly stable from adolescence to late adulthood, but only moderately stable in young children. Stability decreases with increasing time intervals and varies across different cognitive abilities. General intelligence was found to be the most stable cognitive ability, but many specific cognitive abilities are similarly stable. These results provide important standards with respect to the "shelf-life" of cognitive test scores across development and time.

Individual differences in cognitive ability are considered to be highly stable over time (e.g., Hunt, 2010; Mackintosh, 1998; Neisser et al., 1996). Researchers describe cognitive ability as "the most stable psychological trait" (Plomin & von Stumm, 2018, p. 149), and numerous studies document a high stability of cognitive ability (e.g., Deary et al., 2000; Larsen et al., 2008; Schalke et al., 2013). This stability is crucial because cognitive ability tests are frequently used to inform treatment and intervention decisions that have long-term consequences for individuals. For example, cognitive assessments are used for long-term decisions in educational settings, for instance, with respect to school tracking, provision of special education services for struggling learners, and provision of gifted and talented enrichment opportunities (Gottfredson & Saklofske, 2009; Nettelbeck & Wilson, 2005). Similarly, cognitive assessments frequently inform admissions and personnel selection decisions within work settings (Ones et al., 2017; Salgado et al., 2002) and commonly inform decisions with respect to the most suitable among alternative therapeutic interventions within clinical settings (Taylor et al., 2008). All of these applications build on the assumption that cognitive ability will remain stable over the period that the decision is effective. Otherwise, the fit between the individual and the test-based decision (e.g., selected environment or treatment) may deteriorate (Cronbach & Snow, 1977).

High stability of cognitive ability may not apply equally to all populations, circumstances, and cognitive abilities. It is widely recognized that the stability of cognitive ability varies with age (e.g., McArdle et al., 2002; McCall et al., 1977) and test–retest interval (e.g., Watkins & Smith, 2013), but the exact influence of these moderators over the life span is less clear. Further moderators of stability such as the mean ability level of the sample (Breit, Scherrer, et al., 2021) and the utilized test instrument (Villado et al., 2016) have rarely been examined systematically. Quantifying the stability of cognitive ability and the influence of moderating variables is best achieved by meta-analysis (Deeks et al., 2008). With two exceptions, one confined to 15 longitudinal twin studies and to formal comparisons of general intelligence, broad fluid abilities, and broad crystallized abilities (Tucker-Drob & Briley, 2014), and one confined to general intelligence scores in Wechsler and Stanford–Binet tests before 1990 (Schuerger & Witt, 1989), there has been no comprehensive meta-analysis investigating the stability of cognitive ability. The present study aims to close this gap. Specifically, we integrate the results of longitudinal studies investigating the rank-order stability of cognitive ability and examine the moderating effects of age, test–retest interval, measured cognitive ability, ability level, test instrument, and geographic location. Knowledge of the stability of cognitive ability and the factors that influence it is of great benefit for both application and basic research. Understanding variations in stability, that is to what extent and when there are individual differences in cognitive change, advances test-based decision making and our understanding of cognitive development, healthy cognitive aging (Deary, 2014), and the nature of cognitive ability in general (Rinaldi & Karmiloff-Smith, 2017).

Cognitive Abilities in the Psychometric Framework

Cognitive abilities can be defined as any ability that substantially involves mental functions needed for the correct or appropriate processing of mental information (Carroll, 2009). Their measures are frequently based on psychometric models of cognitive abilities (Mackintosh, 2011). The first psychometric model was devised by Spearman (1904), who ascribed the generally positive correlations between different measures of cognitive ability to one common factor that is associated with every measure, albeit to varying degrees. This factor is called "general intelligence" or "general cognitive ability" (*g*) and comprises "the ability to reason, plan, solve problems, think abstractly, comprehend complex ideas, learn quickly and learn from experience" (Gottfredson, 1997, p. 13). Over the course of the 20th century, a general factor ultimately proved insufficient to explain all covariance between different measures (e.g., Thurstone, 1938). Therefore, current psychometric models of cognitive ability are hierarchical models that include both a set of lower order factors representing more specific abilities and *g* at the apex, reflecting the correlations between those factors (Jensen, 1998; Mackintosh, 2011). The most recent structural model, which integrates prominent precursor models, is the Cattell–Horn–Carroll model of cognitive ability (CHC model; McGrew, 1997; W. J. Schneider & McGrew, 2018). The CHC model differentiates narrow, intermediate, and broad abilities and puts *g* at the apex of the hierarchy. Of the 17 broad abilities, six are classified as "tentative" because they require further research to be included (i.e., emotional intelligence, kinesthetic abilities, olfactory abilities, tactile abilities, psychomotor abilities, psychomotor speed). The remaining, more established broad abilities are described in Table 1; the resulting top two levels of the CHC model are depicted in Figure 1.

Many modern tests of cognitive ability are constructed based on the CHC model or locate their scales in the model. Usually, the tests assess *g* and broad abilities from the CHC, but not all broad abilities are equally represented. A recent analysis showed that virtually all subtests of major cognitive ability tests (i.e., Differential Abilities Scale, second edition; Kaufman Assessment Battery for Children, second edition; Wechsler Intelligence Scale for Children, third, fourth, and fifth editions; Woodcock–Johnson III Tests of Cognitive Abilities) can be factor analytically assigned to *g* and one of six broad abilities. These are comprehension knowledge, fluid reasoning, learning efficiency, processing speed, visual processing, and working memory capacity (Caemmerer et al., 2020). Some of the ability tests were not explicitly developed based on the CHC model, which demonstrates the usefulness of the model to classify the subtests of different instruments.

The Stability of Cognitive Abilities

When investigating the stability of cognitive abilities, four different types of stability can be distinguished (Breit, Scherrer, et al., 2021; Fryer & Elliot, 2007): mean-level change, ipsative continuity, individual-level change, and rank-order stability. First, *mean-level change* describes the average change in a score over time. Cognitive ability generally increases during childhood and adolescence (e.g., McArdle et al., 2002; Schroeders et al., 2015), with abilities that require effortful processing (e.g., fluid reasoning, learning efficiency, processing speed, visual processing, working memory capacity) increasing faster than knowledge-based abilities (e.g., comprehension knowledge; Baltes et al., 1999). After young adulthood, effortful processing–based abilities begin to decrease, whereas comprehension knowledge increases further into late

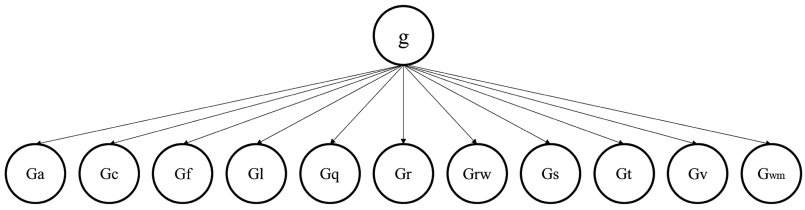
Table 1
CHC Abilities and Their Definitions by W. J. Schneider and McGrew (2018)

Ability	Ability name	Definition
Ga	Auditory processing	The ability to discriminate, remember, reason, and work creatively (on) auditory stimuli, which may consist of tones, environmental sounds, and speech units.
Gc	Comprehension knowledge	The ability to comprehend and communicate culturally valued knowledge. Gc includes the depth and breadth of knowledge and skills such as language, words, and general knowledge developed through experience, learning, and acculturation.
Gf	Fluid reasoning	The use of deliberate and controlled procedures (often requiring focused attention) to solve novel "on the spot" problems that cannot be solved by using previously learned habits, schemas, and scripts.
Gl	Learning efficiency	The ability the ability to learn, store, and consolidate new information over periods of time measured in minutes, hours, days, and years.
Gq	Quantitative knowledge	The depth and breadth of declarative and procedural knowledge and skills related to mathematics.
Gr	Retrieval fluency	The rate and fluency at which individuals can produce and selectively and strategically retrieve verbal and nonverbal information or ideas stored in long-term memory.
Grw	Reading and writing	The depth and breadth of declarative and procedural knowledge and skills related to written language.
Gs	Processing speed	The ability to control attention to automatically, quickly, and fluently perform relatively simple repetitive cognitive tasks. Attentional fluency or attentional speediness.
Gt	Reaction and decision speed	The speed of making very simple decisions or judgements when items are presented one at a time.
Gv	Visual processing	The ability to make use of simulated mental imagery to solve problems—perceiving, discriminating, manipulating, and recalling images in the "mind's eye."
Gwm	Working memory capacity	The ability to maintain and manipulate information in active attention.

Note. CHC = Cattell–Horn–Carroll model of cognitive ability

adulthood and only declines toward the end of life (Horn & Cattell, 1967; Tucker-Drob et al., 2022; Wang & Kaufman, 1993). These changes may not be independent but instead linked through developmental couplings between different cognitive abilities (e.g., Li et al., 2004). Interindividual variance in early cognitive development or cognitive aging (Lövdén et al., 2005) is not captured by this type of stability. Second, *ipsative continuity* represents the stability of an individual's configuration of different scores—their ability profile—over time. Research on age differentiation effects has shown that the strength of cognitive profiles remains relatively uniform across childhood and adolescence and decreases toward the end of life (Breit, Brunner, et al., 2022). There is some tentative evidence that cognitive ability profiles have little temporal stability in low-ability samples (McDermott et al., 1992; Watkins & Smith, 2013) but moderate stability in high-ability samples (Breit, Scherrer, et al., 2021). Third, *individual-level change* represents the change in the test score of an individual. Individual-level change is directly relevant to many practical applications of cognitive ability testing that involve the placement of an individual in an appropriate educational, vocational, or social environment. If an individual exhibits a substantial change in their abilities in any direction, the selected environment may become inappropriate (Cronbach & Snow, 1977). Nevertheless, individual-level change is rarely investigated directly in cognitive ability research. Instead, research mostly focuses on the last and most relevant stability to the present work, *rank-order stability*, also known as differential continuity. It represents the stability of individual differences in cognitive ability and is usually assessed with test–retest Pearson product–moment correlations (e.g., Breit, Scherrer, et al., 2022). With the investigation of rank-order correlations and potential influencing factors, one investigates individual differences in cognitive development over the life span (Deary, 2014). Rank-order stability analyses can also be regarded as an indirect analysis of the frequency of substantial individual-level change. If a sizable percentage of individuals in a sample exhibit large changes in cognitive ability over time, this will affect the overall rank order. Analogously, a high

Figure 1
The Top Two Levels of the CHC Model



Note. The acronyms are defined in Table 1. CHC = Cattell–Horn–Carroll model of cognitive ability.

rank-order stability indicates that the proportion of individuals with major changes relative to other individuals is low.

Genetic influences have been shown to strongly drive the rank-order stability of cognitive ability, with some additional contribution of shared environmental influences that are responsible for both stability and change in cognitive abilities (Bartels et al., 2002). Deary et al. (2012) reported the genetic correlation between cognitive ability in childhood and old age to be as high as .62. A meta-analysis of 15 longitudinal twin and adoption studies supported the notion that both genetic and, to a lesser extent, environmental factors contribute to the rank-order stability of cognitive ability (Tucker-Drob & Briley, 2014). According to their results, genetic influences on phenotypic stability increase during early cognitive development and account for up to 75% of the stability in adulthood, whereas shared environmental influences decrease and nonshared environmental influences slightly increase over the life span. These trajectories mostly conform to theories proposing Gene × Environment interactions in the development of cognitive ability. Such theories propose that (a) based on genetic differences, individuals respond differently to the same environment, and in turn, there may be experience-activated epigenetic processes that are robust over time and (b) individuals systematically experience different environments as a consequence of their genotypes, caused by passive, evocative, and active selection processes (for an in-depth discussion, see Tucker-Drob & Briley, 2014). The findings therefore imply that moderators of rank-order stability can operate both genetically and environmentally.

Early work by Bayley (1949) showed that rank-order stability of cognitive ability increases sharply during early and middle childhood. In line with this finding, Tucker-Drob and Briley (2014) found an increasing stability (test–retest correlation) over the course of childhood in their meta-analysis of twin and adoption studies, from just above .2 in infancy to above .7 by the age of 12 for a test–retest interval of 6 years. Beyond early childhood, many studies have reported substantial stabilities for very long test–retest intervals, including impressive long-term longitudinal studies such as the Scottish Mental Surveys, the Seattle Longitudinal Study, and the Vietnam Era Twin Study of Aging. Findings from the Scottish Mental Surveys, in which children's IQ was first measured at age 11, showed test–retest correlations of .67 for a time span of 59 years and .54 for a time span of 79 years (Deary, 2014; Deary et al., 2013). Based on a different long-term study, Schwartzman et al. (1987) reported a test–retest correlation of .78 between the ages of 25 and 65. Rönnlund et al. (2015) found that cognitive ability level at age 18 accounted for 90% of ability variance at age 50 ($r = .95$) and 74% at age 65 ($r = .86$). Similarly, high test–retest correlations for considerable test–retest intervals in adults were found, for example, by Hertzog and Schaie (1988) and Larsen et al. (2008). Schuerger and Witt (1989) conducted a meta-analysis on the rank-order stability of Wechsler and Stanford–Binet IQ test scores based on 34 studies and reported a mean test–retest correlation of .82. Even in very old adults, studies have reported evidence for substantial stability. For example, based on data from the Virginia Cognitive Aging Project, Salthouse (2012a) reported 3-year stability estimates in adults aged 80–97 ranging from .63 to .80 for different cognitive abilities.

The available empirical findings therefore point to a substantial long-term rank-order stability of cognitive abilities, but the precise estimates vary. A number of potential moderating variables like age, time span between measurements, or assessed ability may explain this heterogeneity. Therefore, a comprehensive meta-analysis is needed to reliably quantify the stability of cognitive abilities and the influence of potential moderator variables.

Potential Moderators of the Rank-Order Stability of Cognitive Abilities

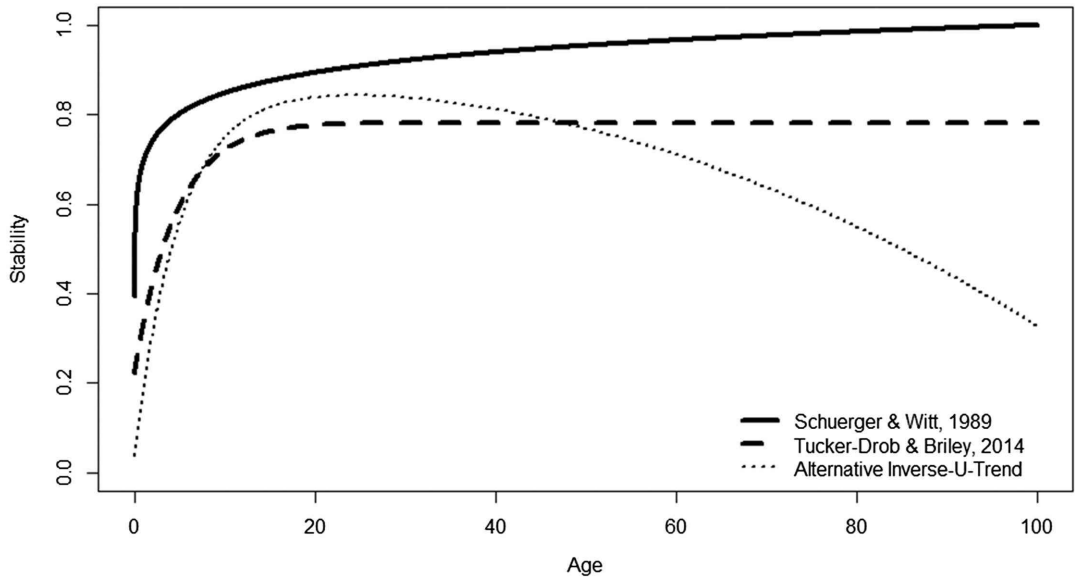
Age

Systematic changes in the rank-order stability of cognitive ability across the life span have been demonstrated many times. The predominant view in the literature is that cognitive tests taken in infancy have little predictive value for later cognitive ability but that the stability rapidly increases during early cognitive development until almost no reordering occurs anymore by early adulthood (Tucker-Drob & Briley, 2014). The rapid increase in stability during childhood was already described by Bayley (1949), who found hardly any stability in infancy but stabilities over .90 at age 13. Schuerger and Witt (1989) investigated age as a moderator in their meta-analysis of rank-order stability of *full-scale IQ test* scores, finding a positive and statistically significant logarithmic trend (solid line in Figure 2). This finding implies a steep increase in stability between ages 3 and 15 that slowly diminishes thereafter but is maintained throughout adulthood. Tucker-Drob and Briley (2014) tested the fit of different functional forms for the age trend in rank-order stability of a variety of cognitive abilities, finding the best fit for an exponential function that again implied a rapid increase of stability during childhood closely approaching an asymptote after early adulthood with no further increase (dashed line in Figure 2). Notably, both analyses did not include samples of very old participants, with maximum sample ages of 65 and 73 years, respectively. Yet, it is possible that some reordering occurs in old age, as different factors may contribute to cognitive decline than those that contribute to cognitive changes in earlier development (e.g., Li et al., 2004). Moreover, in their two-component theories of intellectual development, Lindenberger and Baltes (Baltes et al., 1999; Lindenberger & Baltes, 1994) predicted that cognitive aging should be associated with a partial reordering of individual differences in cognitive abilities. They hypothesized that increased reordering will occur whenever there is greater mean-level change in cognitive development (i.e., early childhood and late adulthood) because greater mean-level change is expected to be associated with greater increases in novel variation per unit of time. This reordering would imply a decrease in stability in old age, meaning that the stability trajectory may in fact be best described by an inverse U-shaped function (dotted line in Figure 2) with increases in childhood and decreases in old age. In line with this idea, some studies reported only modest stabilities in very old samples (e.g., Ghisletta & Lindenberger, 2003; Gregory et al., 2009). Conversely, there is also some evidence for the high stability of cognitive ability in very old adults (e.g., Hopp et al., 1997), underscoring the need for meta-analytic investigation across the life span.

Test–Retest Interval and Its Interaction With Age

A general effect of the duration of the test–retest interval on the rank-order stability estimate is well established. Interestingly, the effects of the interval duration do not appear to be linear. Instead, at

Figure 2
Some Possible Age Moderation Trends



Note. Age moderation of rank-order stability of cognitive abilities in Schuerger and Witt (1989), Tucker-Drob and Briley (2014), and an example of an alternative inverse U-shaped moderation trend expected based on a model in which stability is inversely related to the absolute magnitude of mean change.

first, there is a steep decrease in stability with increasing interval, after which even large increases in the test–retest interval have little additional effect on stability (Schuerger & Witt, 1989; Tucker-Drob & Briley, 2014). Whereas Schuerger and Witt (1989) investigated age and interval effects separately, Tucker-Drob and Briley (2014) stressed the importance of considering the effect of the interval in relation to the age of the sample. This dependence was already observed by Bayley (1949), who found that stability deteriorates quickly in infants and young children with increasing test–retest interval but is much more persistent in adolescents. Tucker-Drob and Briley (2014) focused on childhood and adolescence in their interaction analyses because of their sparse data in adulthood. They found a more pronounced time decay effect for younger ages, albeit not statistically significant. Comparable analyses for older samples or larger age ranges are lacking.

Cognitive Ability Captured

The stability of cognitive ability may depend not only on the age of the participants and the test–retest interval but also on the captured cognitive ability. First, *g* might be more stable than more specific abilities, that is, the broad abilities of the CHC model. Higher level abilities such as *g* that are measured by a multitude of different tasks are less likely to be affected by specific learning experiences or activities, whereas lower level abilities may be more dependent on acquired knowledge and skills and therefore more easily changed by experience, leading to lower stability (Reeve & Bonaccio, 2011; Tucker-Drob & Briley, 2014). The lower stability of broad ability scores as compared to *g* has been shown in individual studies (McDermott et al., 1992; Watkins & Smith, 2013) and meta-analytically for children (Tucker-Drob & Briley, 2014). Moreover, Tucker-Drob and Briley (2014) proposed that various broad abilities are dependent on genetic and environmental factors to different degrees, potentially also leading to differences in stability between them. When grouping abilities as either "fluid," characterized by effortful processing, or "crystallized," characterized by knowledge dependency, they found no significant differences in their stability. However, this analysis was based on relatively sparse data (i.e., 33 and 21 effect sizes for fluid and crystallized abilities, respectively). Following the CHC model, it is necessary to investigate all broad abilities individually, as they are assumed to rely on somewhat distinct neurological functions and serve different purposes in human survival and reproduction (W. J. Schneider & McGrew, 2018). Broad abilities may differ in their developmental trajectories and stabilities beyond an effortful processing versus knowledge divide. Ideally, not only the mean stabilities but also the stability trajectories across the life span are investigated for each broad ability. This kind of meta-analytic investigation naturally requires a very broad database.

General Cognitive Ability (g) Level

The ability differentiation hypothesis states that the structure of cognitive ability changes across the continuum of the general cognitive ability *g*. Whereas the overall factor structure appears to be constant, the relative importance of *g* for individual test performances decreases with increasing *g*-level (Breit, Brunner, et al., 2022; Tucker-Drob, 2009). This ability differentiation effect implies a decrease in systematic variance in measures of general intelligence with increasing *g*-level, leading to a gradual reduction of test-score reliability (Breit, Brunner, et al., 2022). Because test–retest correlations cannot exceed the reliability of the utilized test,

this may cause lower estimates of rank-order stabilities of *g* in higher ability samples. Up to now, there are no systematic investigations of differences in the stability of *g* depending on the ability level.

Test Instrument

Cognitive ability tests vary considerably in content. One important distinction is that between unidimensional and multidimensional tests. Unidimensional tests aim to measure *g*, often by using a single type of task like figural reasoning tasks (e.g., Raven, 1938). Multidimensional test batteries aim to measure a variety of cognitive abilities with specific subtests; usually, they also provide a *g*-score as an average score (e.g., Wechsler, 2003). Multidimensional test batteries show heterogeneity in terms of test size (i.e., number of subtests and tasks), task presentation (i.e., oral by the administrator or in writing), test setting (i.e., individual or group test), test reliability, as well as which specific abilities are measured, in which order, and how they are weighted. All these factors may affect the test–retest correlation of test scores, but systematic investigations are lacking. In one study, greater stability was found for the full test scores of the multidimensional Wonderlic Personnel Test than for the unidimensional Raven's Advanced Progressive Matrices (Villado et al., 2016).

Sometimes, test administrators use a different test at a second administration either to avoid retest effects (i.e., training or memory effects) or because the test used at first testing cannot be used for the age range of the tested sample at retest. In the latter case, it is often possible to use a test from the same test family that is constructed similarly but was adjusted to the target age (e.g., different Wechsler tests). Stability estimates may differ systematically between the same test, a test from the same test family, or a different test being used at retest because the test–retest correlation is limited by the size of the concurrent correlation of both tests.

Finally, it is important whether a whole test battery is used or only parts of it. In many scientific investigations, subtests from one or more tests are selected to measure the constructs of interest economically. Test batteries may not only be shortened in testing practice but also augmented, although this happens less often. The CHC cross-battery assessment approach entails "augment or supplement any major ability test to ensure measurement of a wider range of broad and narrow cognitive abilities in a manner that is consistent with contemporary theory and research and that is predicated upon sound psychometric principles" (Flanagan et al., 2012, p. 459). The stability estimates may be affected by such a shortening or extension of existing test instruments because test reliability varies with test length.

Geographic Location

Geographic location is often accompanied by differences in culture, language, educational systems, economic opportunities, nutrition, health care, social mobility, or physical living environment. As environmental factors contribute to stability, these differences and their respective combinations can affect the stability of individual differences in cognitive ability (Tucker-Drob & Briley, 2014). To our knowledge, there are no systematic comparisons of differences in rank-order stabilities between different countries, regions, or cultures.

Test Reliability

Test–retest correlations (i.e., rank-order stabilities) rely on the reliability of the tests to measure the construct at both times of measurement. They cannot exceed the square root of the product of both reliability coefficients. Alternatively put, stability coefficients are reduced by measurement error (i.e., unreliability of the tests). This fact has important implications for the present meta-analysis, as, without adjustment for test reliability, stability will be underestimated. For example, Hopkins and Bibelheimer (1971) reported substantially larger disattenuated test–retest correlations (.55–.94) than uncorrected correlations (.33–.81). Moreover, moderator analyses may be biased by test reliability if there is a systematic relationship between the moderator variable and test reliability. For example, cognitive ability tests and the testing situation must be modified in various ways to be appropriate for young children. If these modifications result in systematic differences in test reliability between different age groups, and reliability is not adjusted for, these age trends in reliability may be confused for age trends in stability. Similarly, reliability may also differ between tests of different abilities. Systematic differences in captured cognitive abilities, length, speededness, and response format in tests of different abilities may affect test reliability (Hong & Cheng, 2019; Symonds, 1928). For example, processing speed tasks are constructed very differently from tests of comprehension knowledge. Like individual subtests for different abilities, entire test batteries vary in content, length, speededness, and response format, leading to differences in reliability. That is, the scores from different test instruments or batteries (e.g., the Wechsler tests vs. the Woodcock–Johnson tests) may appear to differ in stability because of differences in their reliabilities. Approaches for disattenuating stability estimates from measurement error are therefore important both for estimating the stability of true scores and for obtaining unbiased estimates in moderator analyses. We are not aware of any meta-analytic investigation of the stability of cognitive abilities that adjusted for test reliability.

The Current Meta-Analysis

Previous meta-analyses of the rank-order stability of cognitive ability provided valuable insights into the stability of *g* in Wechsler and Stanford–Binet tests (Schuerger & Witt, 1989) and the contributions of genetic and environmental influences herein (Tucker-Drob & Briley, 2014). However, due to their specific research questions and an associated narrow selection of studies, they were limited in the age range (maximum baseline age of 65 and 73 years, respectively), captured cognitive ability (*g*, Gf, Gc), and test instruments (Wechsler and Stanford–Binet tests). Relatedly, some moderators were investigated with relatively sparse data (e.g., cognitive ability captured) or not at all (e.g., mean *g*-level of the sample, geographic location). Further, in both meta-analyses, there was no adjustment for test reliability.

The aim of the present study therefore is to provide a comprehensive analysis of the available evidence by meta-analyzing the findings of longitudinal studies that investigate the rank-order correlation (i.e., rank-order stability) of cognitive ability and that cover the entire life span from 1 to 90 years. All hypotheses and analyses were preregistered except Hypothesis 10 and the

associated analyses (https://osf.io/2pn3x). We investigated the following hypotheses:

Hypothesis 1: (a) Rank-order stability decreases with increasing *test–retest interval*. (b) The decrease per additional year diminishes with increasing intervals. In addition, we exploratory tested whether this effect can be better described with a linear, a quadratic, or an exponential function.

Hypothesis 2: Rank-order stability varies with *age*. (a) Over all life stages, *age* is nonlinearly related to stability. We expected that rank-order stability increases with age in preschool children and in school-aged children and adolescents, remains constant in adults, and decreases in elderly individuals. We tested whether this effect can be better described with a linear function, a quadratic function, a connected linear spline, or an exponential function. (b) As an open research question, we investigated the interaction effects between *test–retest interval* and *age*.

Hypothesis 3: The average rank-order stability of cognitive ability is higher than that of other (noncognitive) personality traits across the life span, controlling for the test–retest interval.

Hypothesis 4: The rank-order stability varies with *captured cognitive ability*: The stability is higher for measures of *g* than for measures of CHC broad abilities.

Hypothesis 5: The rank-order stability of *g* decreases with increasing *g-level*. The relation of rank-order stabilities of CHC broad abilities and *g*-level was investigated as an open research question.

Hypothesis 6: As an open research question, we investigated whether the rank-order stability of cognitive ability varies with the *test instrument* used.

Hypothesis 7: (a) The rank-order stability of cognitive ability is higher when the same test was used for both measurements compared to varying measurement instruments from the same test families or varying tests. (b) The rank-order stability of cognitive ability is higher when measurement instruments from the same test families were used compared to varying tests.

Hypothesis 8: The rank-order stability of cognitive ability is higher when the complete test battery is used compared to a selection of subtests.

Hypothesis 9: As an open research question, we investigated whether the rank-order stability of cognitive ability varies between countries.

Hypothesis 10: As an open research question, we investigated whether the results of the analyses for Hypotheses 2, 3, 4, and 6 are replicated in a sample of effect sizes corrected for test reliability.

Method

Transparency and Openness

We report how we determined our sample size, all data exclusions, all manipulations, and all measures in the study. Because no human or animal participants were involved in the study, ethics committee approval was not sought. We adhered to the Preferred Reporting Items for Systematic Reviews and Meta-Analyses 2020 guidelines for systematic reviews (Page et al., 2021). All data and research materials are available at https://osf.io/ajufs/. This meta-analysis was preregistered (https://osf.io/2pn3x). Any deviations from the preregistration are reported in Supplemental Materials.

Identification and Screening Process

The literature search for longitudinal studies reporting rank-order stability of cognitive abilities over time was conducted following the guidelines by Johnson and Hennessy (2019) and in consultation with a research librarian at the University of Trier. Figure 3 depicts a Preferred Reporting Items for Systematic Reviews and Meta-Analyses chart (Page et al., 2021) of the preliminary identification and screening process.

Overall, we identified 4,077 different records based on five search strategies: (1) search for peer-reviewed articles in APA PsycInfo; (2) search for books in APA PsycInfo; (3) search for dissertations in APA PsycInfo; (4) search for peer-reviewed articles in ERIC; (5) reference lists of relevant reviews and meta-analyses identified in Steps 1–4. In Search Strategies 1–4, we used the following keywords as the search string:

(Intelligence* or cognitive abilit* or mental abilit* or IQ or g factor or mental test* or gma or fluid reasoning or comprehension knowledge or gf or gc).ti,ab. AND (longitudinal or stabilit* or retest* or repeated measur* or cross-lagged or autocorrelation* or long term or "change over time").ti,ab. AND (not autism not dement* not artificial not emotional intelligence* not social intelligence* not schizophrenia not infant not disorder not lesion* not animal* not disabilit* not sexual abuse not depress* not defect* not injur* not ADHD not experiment* not medication* not drug* not stimulant* not mental illness* not senile* not disease* not patient* not therap* not concussion* not stroke* not malnourish* not syndrome* not robot* not manipulat* not aphasia).ti,ab.

In Search Strategy 5, we used the references of four relevant reviews or meta-analyses that were identified by Search Strategies 1–4.

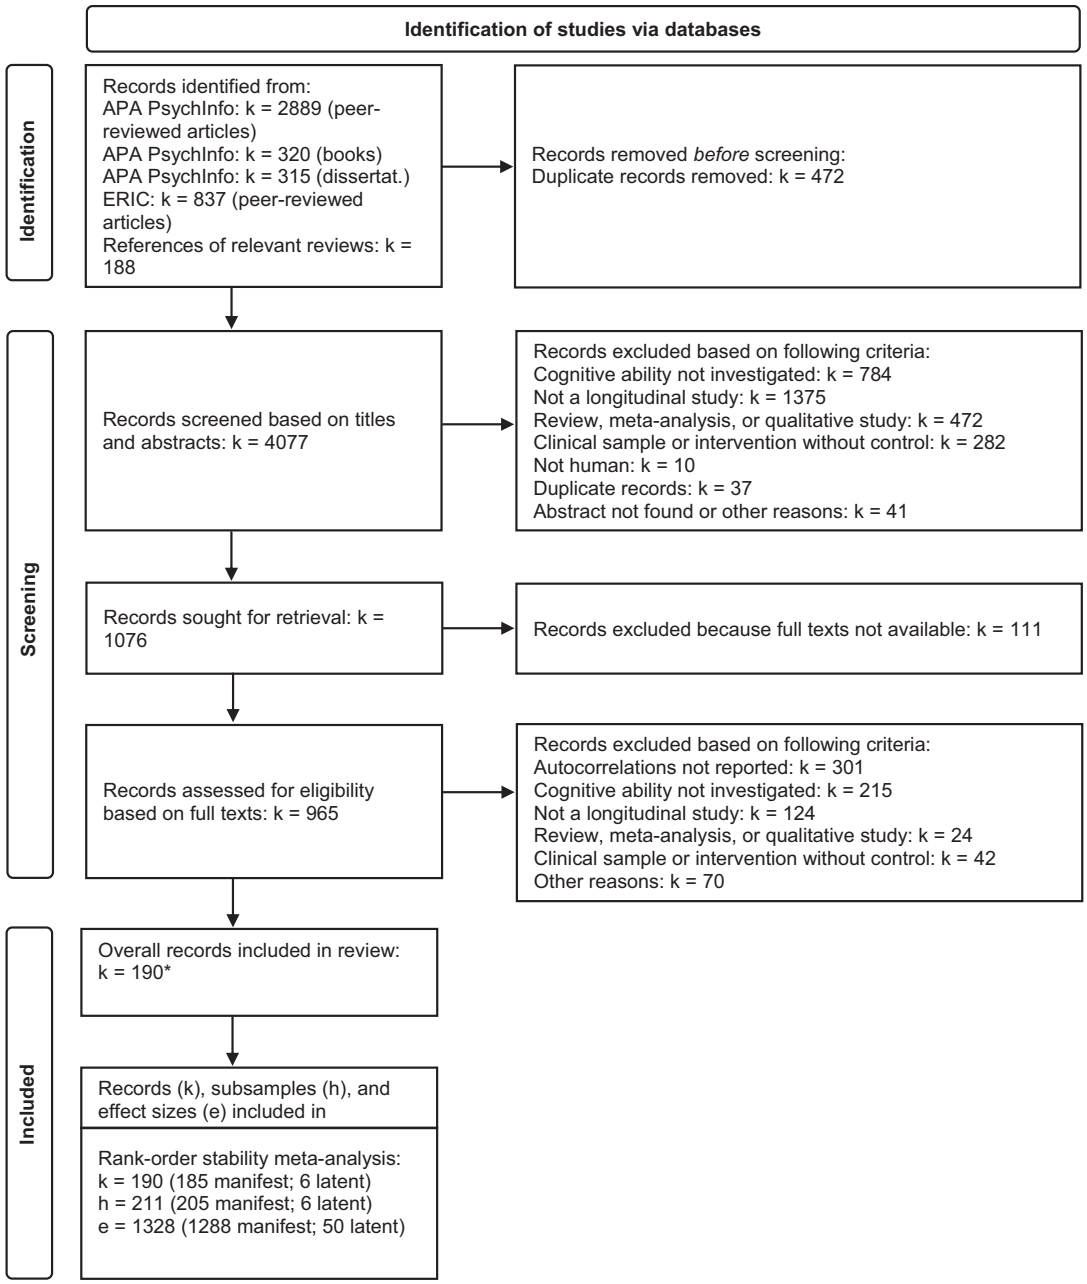
The following inclusion and exclusion criteria were applied to the identified records:

1. Cognitive ability was assessed, and ability scores were as follows: (a) full-scale test scores from tests developed and standardized to measure cognitive ability; (b) composite scores comprised of subtests measuring one specific cognitive ability, taken from a test developed and standardized to measure cognitive ability; or (c) composite scores derived from test batteries comprised of individual scales all developed and standardized to measure cognitive ability. Screenings reported to be shorter than 10 min were excluded.

2. Cognitive ability was assessed longitudinally, and the same ability was assessed at all times of measurement (e.g., Gf). The minimum acceptable test–retest interval was 1 day.

3. The study reports primary analyses as opposed to integrative secondary analyses in meta-analyses or reviews.

Figure 3
Study Identification and Screening Process as a PRISMA Chart



Note. This figure presents the literature search and gives information on the number of coded studies and effect sizes. k = number of records, h = number of included samples, e = number of effect sizes; PRISMA = Preferred Reporting Items for Systematic Reviews and Meta-Analyses.
[a] One additional record (one subsample, six effect sizes) was added after suggestion by a reviewer.

4. The study did not investigate a clinical sample and did not apply an intervention to all participants between measurements.
5. The study examined a sample that covered a sufficiently narrow age range. An age range was considered sufficiently narrow if it did not include more than two of seven predefined, partially overlapping life stages: infants (0–3), preschool (3–7), elementary school (5–14), secondary school (10–20), young adults (16–25), adults (25–70), and old age (70–100).
6. The test–retest intervals in the study were sufficiently homogeneous. The range of test–retest intervals was

considered too large if the standard deviation of the interval was more than half the size of the mean interval length.

7. The study examined human participants.

All 4,077 articles, dissertations, or book chapters were first screened for eligibility based on titles and abstracts by two of the project researchers and four trained student assistants. One project researcher validated the ratings of the coauthors in a randomly assigned subsample of 250 records. Interrater agreement was 91.20%, and all discrepancies were resolved through discussion. Next, two of the project researchers and four trained student assistants assessed 965 studies for eligibility based on the full text. Note that we contacted the corresponding authors of studies published in 2010 or later if rank-order stabilities were not reported to obtain these missing values. We contacted the authors of 100 studies, 33 of which responded, leading to inclusion in the meta-analysis. A table presenting the studies included and excluded during the full-text screening process can be found in the Open Science Framework directory (https://osf.io/ajufs/). One researcher validated the ratings of the coauthors in a randomly assigned subsample of 50 records. Interrater agreement was 94%, and all discrepancies were resolved through discussion. A total of 190 different records remained at the conclusion of the screening process; 185 of them included 205 samples and provided 1,288 rank-order stability effect sizes based on manifest values. Six records including six samples provided 50 rank-order stability effect sizes based on latent factor scores. We only included studies reporting latent correlations if standard errors (*SE*s) for the relevant effects were available. Note that rank-order stability effect sizes based on manifest values and latent factor scores were investigated separately because these effect sizes are not comparable (i.e., in contrast to manifest values, latent factor scores are corrected for measurement error).

Coding Procedure, Study Variables, and Subdata Sets

All records were coded on the variables described below by four trained student assistants, and one project researcher controlled each coding. As many studies contained multiple scales that were assigned to different broad CHC abilities and/or several measurement points, we often estimated multiple effect sizes based on one sample. All variables were coded on the effect size level. The complete data set including all moderator variables is available as an Excel sheet at https://osf.io/ajufs/. Detailed information on the 205 samples providing rank-order stability effect sizes based on manifest values is presented in the Supplemental Materials (Supplemental Table S1). The frequencies of the study variables are reported in Supplemental Table S2.

Study Variables

Effect Size

Autocorrelations r_{tt} of participants' cognitive ability scores over time were coded as effect sizes of rank-order stability (e.g., r_{tt} of Gf at T1 with Gf at T2). If a study reported several measurement points, all possible combinations of r_{tt} were coded. For example, if three measurement points were reported, three r_{tt} effect sizes corresponding to the correlations of T1 with T2, T1 with T3, and T2 with T3 were coded. In manifest correlations, effect size variance was estimated according to the following formula (Borenstein et al., 2009, p. 41; Hedges & Olkin, 2014).

$$V_{r_{tt}} = \frac{(1 - r_{tt}^2)^2}{n - 1}. \quad (1)$$

In latent correlations, effect size variance was calculated by squaring the *SE*. In the following, we labeled the averaged rank-order stability ρ because ρ is the population parameter of *r* (Borenstein et al., 2009; Hedges & Olkin, 2014).

Publication Type

Publication type was coded as a dichotomous variable (i.e., 0 = peer-reviewed journal article; 1 = no peer-reviewed journal article).

Sample Size n

For each effect size, we coded the respective sample size *n* as a continuous variable. If available, we coded the overlapping *n* of T1 and T2. If only *n* of T1 and *n* of T2 were available, we coded the smaller *n* as an estimate of the overlapping *n*. If only *n* of T1 or *n* of T2 was available, we coded the available *n* as an estimate of the overlapping *n*.

Test–Retest Interval

For each effect size, we coded the test–retest interval between the measurement points as a continuous variable in years. In cases where the duration was reported precisely to the day, we coded it accordingly (i.e., a 1-month interval was defined as .083 years). We subtracted 5 from the test–retest interval and used this new variable instead of the test–retest interval in all subsequent analyses. Thus, the parameters in our metaregressions represented a 5-year interval instead of a 0-year interval thereby allowing a more meaningful interpretation.

Age

The mean age of the study participants at the first measurement point was coded as a continuous variable in years. If the exact information regarding participants' age was missing, we used other available information from the sample description (e.g., grade level) to estimate a plausible age if possible. We subtracted 20 from age and used this new variable instead of age. By this operation, the parameters in subsequent metaregressions corresponded to an age of 20 years instead of an age of 0 years. This rescaling allowed for a more meaningful interpretation of the parameters because the stability at age 20 is more relevant to practical testing contexts than the stability in newborns where cognitive ability testing is not feasible. In addition, we calculated the quadratic form of age by squaring this variable.

Life Stage

Life stages were coded to allow modeling the age moderation effect in terms of a connected linear spline. The effect sizes referred either to preschool children, school-aged children and adolescents,

adults, older adults, or to elderly individuals at T1. We assorted the effect sizes to one of these categories based on the reported age. Samples with age ≤6 years were assorted as preschool children. Samples with ages >6 and ≤18 years were assorted as school-aged children and adolescents. Samples with ages >18 and ≤65 years were assorted as adults. Samples with ages >65 and ≤80 years were assorted as older adults. Samples aged >80 years were assorted as elderly (Lindenberger & Staudinger, 2018). For the categories preschool children, school-aged children, adolescents, adults, older adults, and elderly, we calculated five connected linear spline variables by following the approach of Tucker-Drob and Briley (2014). These variables represent the linear age differences within these life stages, meaning that a linear age moderation trend was modeled separately for each spline section (i.e., age group). They were calculated as follows:

Preschool Children Spline (Age_1). If age is ≤6, then age_1 = age; if age is >6, then age_1 = 6.

School-Aged Children and Adolescents Spline (Age_2). If age is ≤6, then age_2 = 0; if age is between >6 and ≤18, then age_2 = age − 6; if age is >18, then age_2 = 12.

Adult Spline (Age_3). *If* age is ≤18, then age_3 = 0; if age is between >18 and ≤65, then age_3 = age − 18; if age is >65, then age_2 = 47.

Old Adult Spline (Age_4). If age is ≤65, then age_4 = 0; if age is between >65 and ≤80, then age_4 = age − 65; if age is >80, then age_4 = 15.

Elderly Spline (Age_5). If age is ≤80, then age_5 = 0; if age is >80, then age_5 = age − 80.

This procedure transformed the age values of the effect sizes in each spline section to values ranging from zero to the age range value of the spline (e.g., 18–65 years results in an age range of 0–47 years). Age values less than the minimum value of the respective spline were set to zero, and age values greater than the maximum value of the spline were set to the value of the age range of the spline.

Cognitive Ability Captured

The effect sizes were classified into subcategories of specific CHC broad abilities or general intelligence. We computed one dichotomous dummy variable for each subcategory of captured cognitive ability (e.g., Gf: 1 = captured cognitive ability is Gf; 0 = captured cognitive ability is not Gf). In subsequent moderator analyses, we used *g* as the reference category.

General Cognitive Ability Level at T1

If available, we coded the mean IQ score ($M = 100$, $SD = 15$) at the T1 score as a continuous variable. Sometimes the mean general cognitive ability level was reported as *z* or *t* scores. We converted these scores into IQ scores.

Test Instrument

Different test instruments that were used in at least four samples were coded as separate dichotomous dummy variables (e.g., Culture Fair Test [CFT]: 1 = instrument is CFT; 0 = instrument is not CFT). All instruments that were used in less than four samples were subsumed into one further dichotomous dummy variable representing all other instruments. In the subsequent moderator analyses, the most frequently used test instrument was used as the reference category.

Varying Measurement Instruments

Test and retest measurements of cognitive abilities were either carried out with the same instrument (e.g., CFT at T1 and T2), with instruments from the same test family (e.g., Wechsler Intelligence Scale for Children–Revised at T1 and Wechsler Adult Intelligence Scale, third edition at T2), or with different instruments (e.g., Stanford–Binet at T1 and WISC-III at T2). We coded one dichotomous dummy variable for each of these categories (e.g., same test family: 1 = T1 and T2 were measured with tests from the same test family; 0 = T1 and T2 were not measured with tests from the same test family). In the subsequent moderator analyses, the category referring to the use of the same instrument was used as the reference category.

Complete Test Battery

Measurements of cognitive abilities were either carried out with a complete test battery or based on a selection of subtests from one or more tests. Note that we excluded all studies that used just one single subtest as an estimate of cognitive ability because these did not satisfy our criteria for a valid cognitive ability measure (e.g., only the mosaic cube test from WISC as an estimate of Gv). Complete test was coded as a dichotomous dummy variable (1 = cognitive ability was estimated based on a selection of subtests; 0 = cognitive ability was estimated based on the complete test).

Geographic Location

Studies were conducted in different countries. We subsumed these countries into the following four separate dichotomous variables according to their geographic location: North America (United States and Canada), Europe (all European countries; e.g., France), and Asia (all Asian countries; e.g., Japan). Countries from South and Central America, Oceania, and Africa were carried out in less than four samples each and therefore were coded together as one dichotomous dummy variable representing other locations (i.e., Australia, Congo, Ecuador, Guatemala, and New Zealand). In the subsequent moderator analyses, the category North America was used as the reference category because most effect sizes referred to this geographic location.

Reliability

Test scales have varying degrees of reliability. To control an effect size for reliability, reliability estimates must be available for both the test and the retest. We first searched all records for estimates of reliability (internal consistency Cronbach's α or split-half reliability) based on the sample studied. As these were rarely available, we also used the information provided in the test manuals. We determined that the reliability estimates given in the manuals were only appropriate if the respective test scales were used and scored in accordance with the manuals.

Subdata Sets

Before conducting analyses, we transformed the complete data set into 10 subdata sets based on *g* and the CHC broad abilities that referred to the effect sizes (i.e., *g*, Ga, Gc, Gf, Gl, Gq, Grw, Gs, Gv,

and Gwm). This transformation was essential because we aimed to report all analyses not only for the entire data set but also for each broad ability separately. The frequencies of the study variables in the full data set and the subdata sets are reported in Supplemental Table S2. Detailed descriptive statistics of the data set are provided at the outset of the Results section.

Analyses

The goal of this meta-analysis was to summarize findings from longitudinal studies reporting rank-order stability in cognitive abilities throughout the life span. In many cases, we estimated more than one effect size based on one sample, leading to a clustered data structure with a large number of partly dependent effect sizes within a smaller number of samples. To address this nested data structure, we applied robust variance estimation (RVE) with the robumeta package in R to control for the dependency of effect sizes within studies (Hedges et al., 2010; Tipton, 2013). Of note, some of our analyses were not possible in robumeta. Therefore, when necessary, we also used other R packages or Mplus and clearly denote these occurrences in the following paragraphs.

Moderator analyses were only calculated in the subdata sets that included at least four study samples for moderators because a minimum of four *df* is recommended for RVE metaregressions (Tipton, 2015). Similarly, we only reported the results of moderators if the *df* of an effect was ≥4.

Preanalyses

Outlier Analyses. Because methods for outlier analyses with RVE are not yet available, we performed outlier analyses using the influence function of the metafor package in R (Viechtbauer, 2010) based on a simple random-effect model in the complete data set including all effect sizes. Outliers were identified using the studentized residuals, which are the ratio of a raw residual and the sampling variance of the raw residual (Viechtbauer & Cheung, 2010). All effect sizes with absolute studentized residuals larger than 1.96 were checked for coding errors and plausibility. The influence of the identified outliers was tested by calculating Cook's distance, which tests whether the average effect changes after excluding the considered outlier (Viechtbauer & Cheung, 2010). Viechtbauer and Cheung (2010) recommended using the identified influential outliers for sensitivity analyses rather than routinely deleting effect sizes based on influence statistics (i.e., based on a significant Cook's distance). Therefore, we did not routinely exclude effect sizes with significant Cook's distance but used these values for robustness tests of the magnitude of rank-order stabilities (for more information, see Hypothesis 3 analyses). We only excluded outlier effect sizes that were implausible (i.e., negative autocorrelations).

Publication Bias. Publication bias occurs in meta-analyses when an unrepresentative proportion of significant studies showing a positive direction are included in the analyses (Duval & Tweedie, 2000; Egger et al., 1997). We applied multiple methods to test for publication bias.

We calculated funnel plot analyses and trim-and-fill analyses of effect sizes in the complete data set and the subdata sets. Because funnel plot analyses using RVE are not yet available, we aggregated multiple effect sizes from the same studies and conducted funnel plot analyses with the funnel function of the metafor package. Before calculating funnel plots and performing trim-and-fill analyses, we residualized the effect sizes for age and test–retest interval effects to ensure that any identified asymmetry in the plots was not caused by these moderating variables. We used the best-fitting age and test–retest interval functions (see Hypotheses 1 and 2). In addition, *r* effect sizes were transformed into Fisher's *z* effect sizes because *r* variance (V_r) depends on the magnitude of *r* and therefore would lead to biased funnel plots (see Equation 1). Note that Fisher's *z* variance (V_z) does not depend on the magnitude of *z* (see Equation 2).

$$V_z = \frac{1}{n - 3}. \tag{2}$$

Last, we examined whether the type of publication (i.e., peer-reviewed journal article vs. non-peer-reviewed journal article) significantly moderated stability. We calculated a random-effect RVE metaregression analysis based on the complete data set, as well as based on the subdata sets of *g* and Gf including type of publication as a dichotomous moderator. Note that the other subdata sets contained fewer than four samples from non-peer-reviewed journal articles.

Main Analyses

Hypothesis 1: Test–Retest Interval. We used Mplus and followed the approach by Tucker-Drob and Briley (2014) to investigate linear (Hypothesis 1a) and nonlinear effects (i.e., quadratic, exponential; Hypothesis 1b) of the test–retest interval on stability. Equations for these models are presented in Supplemental Table S5. We had to use Mplus instead of RVE in these analyses because exponential functions in RVE are not yet available in robumeta. Note that the approach of Tucker-Drob and Briley (2014) also applies cluster robust standard errors to account for nested data by the type is complex command in Mplus. Furthermore, this approach provides model fit indices that allow for a comparison of the different effect forms (i.e., to compare linear, quadratic, and exponential effects). To make these results comparable to the RVE analyses, we used the weighting formula from robumeta (Hedges et al., 2010; Tipton, 2013) in Mplus (Equation 3).

$$w = \frac{1}{k(\mathrm{Var} + \tau^2)}. \tag{3}$$

In the original analyses by Tucker-Drob and Briley (2014), the weighting formula did not include the between-sample variance τ^2 (Equation 4).

$$w = \frac{1}{k \times \mathrm{Var}}. \tag{4}$$

To enter τ^2 into the Mplus analyses, we estimated the same models with robumeta and used the estimated τ^2 from these analyses. To keep model fit indices comparable between the linear, quadratic, and exponential models, we entered the same τ^2 as an approximation into all Mplus models (i.e., the τ^2 from the quadratic model). To find the best-fitting test–retest interval form, models were evaluated based on the Bayesian information criterion (BIC) fit index (smaller BIC values indicate a better fit to the data).

Hypothesis 2: Age. We used Mplus and followed the approach of Tucker-Drob and Briley (2014) to estimate the effects of age on stability. In the first step, linear, quadratic, connected linear spline, and exponential effects of age were investigated without including further predictor variables. To find the best-fitting age form, models were evaluated based on the BIC fit index. In the second step, the models with the best-fitting age form were controlled by the best-fitting test–retest interval form. That is, stability was simultaneously predicted by age and test–retest interval. In the third step, the continuous interaction effects between test–retest interval and age were also entered into the model. Interaction effects were evaluated by comparing the BIC fit indices of models from Step 2 and Step 3. Last, the same three steps were repeated based on subsamples of preschool children, school-aged children, and adolescents to explore whether interaction effects of age and test–retest interval can be discovered in these more restricted age groups.

Residualizing Out Test–Retest and Age Effects Before Conducting Hypotheses 3–9. Before testing Hypotheses 3–9, we took into account differences between the effect sizes on test–retest interval and age so that the variation in rank-order stability between data sets, samples, and effect sizes could not be explained by varying test–retest interval and age. This modification was done by residualizing each effect size for test–retest interval and age effects based on the functional forms that were found to be best fitting in Hypotheses 1 and 2 (for the exact formula, see the Result section). After this process, each effect size referred to an expected stability for a test–retest interval of 5 years and a sample age of 20 years. That is, the parameters of the RVE metaregressions based on the residualized effect sizes represent the average stability ρ for a test–retest interval of 5 years and for a sample age of 20 years. Note that the residualization process was only carried out in the complete data set, whereupon the complete data set was divided into subdata sets based on the CHC broad abilities that referred to the effect sizes. Residualizing out test–retest interval and age separately in each subdata set would sometimes lead to implausible results because in some small subdata sets that comprised only a few samples, implausible functions for test–retest interval or age were estimated (e.g., in Grw, test–retest interval positively moderated the stability. For more detail, see Hypothesis 1 Results section).

Hypothesis 3: Magnitudes of Rank-Order Stabilities. We estimated the magnitude of rank-order stabilities by calculating intercept-only random-effect RVE metaregressions based on the complete data set and the subdata sets. We conducted three robustness checks of the magnitude of rank-order stabilities. First, we repeated the analyses without controlling for test–retest interval and age. Second, we repeated the analyses after excluding all influential outlier effect sizes. Third, we repeated the analyses after excluding all effect sizes causing asymmetry (i.e., publication bias observed by Egger's regression).

Hypothesis 4: Cognitive Ability Captured. To test whether captured cognitive ability was associated with the magnitude of rank-order stability, we calculated one random-effect RVE metaregression in the complete data set and included all dichotomous dummy variables for each cognitive ability except for the *g*-factor category of general intelligence. Thus, the *g*-factor category was used as the reference category.

Hypothesis 5: General Cognitive Ability Level. To test whether the stability of *g* decreases with increasing *g*-level, we conducted one random-effect RVE metaregression in the subdata set that referred to *g* and included the mean *g*-level at T1 as a continuous predictor of stability. To test whether the stability of CHC broad abilities increased with increasing *g*-level, we conducted several random-effect RVE metaregressions in the subdata sets that referred to the particular abilities. In these analyses, stability was predicted by the continuous moderator mean general intelligence level at T1.

Hypothesis 6: Test Instrument. To test whether the stability varied by test instrument, we conducted several random-effect RVE metaregressions and included all dichotomous dummy variables for each test instrument as predictors of stability. In the analyses based on the complete data set, *g*, Gc, Gv, and Gwm, the WISC test was used as the reference category because it was the category with the most effect sizes. In the analyses based on Gf, the Raven's matrices test was used as the reference category because it was the category with the most effect sizes. In the analyses based on Gq and Gs, the Woodcock–Johnson test was used as the reference category because it was the category with the most effect sizes.

Hypothesis 7: Varying Measurement Instruments. To test whether the stability differed based on whether varying measurement instruments were used at T1 and T2, we conducted several random-effect RVE metaregressions and included the dichotomous dummy variables of the use of the same test, same test family, and different tests as predictors of stability. In these analyses, the use of the same test was used as the reference category.

Hypothesis 8: Complete Test. To test whether the stability differed depending on whether the complete test battery was used as an estimate of cognitive ability, we calculated several random-effect RVE metaregressions and included the dichotomous dummy variable complete test as a predictor in these analyses. The complete test variable was used as the reference category.

Hypothesis 9: Geographic Location. To test whether the stability varied between geographic locations, we calculated random-effect RVE metaregressions including the dichotomous dummy variable that referred to different geographic location categories. In these analyses, North America was used as the reference category, as it was the category with the most effect sizes.

Hypothesis 10: Using Reliability Estimates to Disattenuate for Measurement Error. Like all correlations, stability coefficients are attenuated by measurement error. If hypothesized moderators of stability (e.g., age) are themselves associated with variation in measurement error, this can lead to spurious results. When estimates of test reliability (e.g., internal consistency) are available, such estimates can be used to correct correlations for measurement error. To test whether the findings from Hypotheses 2, 3, 4, and 6 are robust to corrections for measurement error, we replicated these analyses within a subsample of effect sizes where reliability information was available. Each of these analyses was performed twice. First, we carried out the analyses without adjusting for reliability to demonstrate the original effects within this subsample of effect size. Second, we conducted the analyses after correcting both the effect sizes and the effect variance for measurement error by the following formulas (Borenstein et al., 2009, p. 341).

$$r_{\text{adjusted}} = \frac{r_{\text{original}}}{\alpha}, \tag{5}$$

$$V_{\text{adjusted}} = \frac{V_{\text{original}}}{\alpha^2}. \tag{6}$$

Where α represents the averaged *reliability* ($r_{tt1} + r_{tt2}/2$) of the first and the second measurement.

Exploratory Analyses

Simultaneous Inclusion of All Categorical Moderators. To assess the robustness of our initial findings, we conducted a metaregression analysis that incorporated all categorical moderators simultaneously. This comprehensive approach was driven by chi-square tests that indicated an uneven distribution among these moderators (see the Data Description section).

Age Moderation Analysis Based on Age-Homogeneous Samples. Given that some of the assessed effect sizes were derived from very age-heterogeneous samples, we conducted an age analysis replication with a subset of effect sizes that were exclusively drawn from age-homogeneous samples. In this procedure, we excluded samples with an age *SD* greater than 5 years, or in cases, where the age *SD* was not reported, samples spanning an age range exceeding 20 years. Samples lacking any information about age variation were also excluded. The final analysis incorporated 1,038 effect sizes drawn from 153 samples.

Results

Description of Studies

Supplemental Table S2 reports the descriptive statistics and frequencies of the study variables for the complete data set and for subsets referring to different abilities or latent estimates. Effect sizes were obtained from a wide range of sources including many well-known longitudinal studies of cognitive development and cognitive aging such as the Lothian Birth Cohorts of 1921 and 1936, the Berlin Aging Study, the Seattle Longitudinal Study, the Virginia Cognitive Aging Project, the BETULA Study, the Victoria Longitudinal Study, the Colorado Adoption Project, the Twins Early Development Study, the LOGIC Study, Project Head Start, and the Fullerton Longitudinal Study. We included a substantial number of effect sizes corresponding to test–retest correlations among manifest (i.e., not latent) variables ($e = 1{,}288$) corresponding to a large number of samples ($h = 205$) with a total sample size of $n = 87{,}508$ across all abilities. In addition, we coded 50 latent effect sizes based on six samples with a total sample size of $n = 18{,}107$. The main meta-analysis only included the manifest effect sizes. Thus, the following sections present the results based on the data sets of manifest correlations, while meta-analytic results derived from latent correlations are reported in Supplemental Tables S8 and S9. Unfortunately, the data set based on latent correlations was too small (i.e., $df < 4$) for most moderator analyses. Therefore, these results should be interpreted with great caution.

The mean number of participants per effect size ($M = 440.53$) and the associated standard deviation ($SD = 1391.10$) indicate that our meta-analysis includes, on average, rather large samples and that there is considerable variation in sample size across studies, ranging from $n = 9$ to $n = 15{,}496$. Most effect sizes referred to *g* (650 effect sizes, 151 samples) followed by Gc (195 effect sizes, 76 samples) and Gf (172 effect sizes, 60 samples). Effect sizes based on Ga, Gl, and Grw each referred to fewer than 10 samples, which hinder complex moderator analyses based on these abilities. The data integrated effect sizes over a wide range of test–retest intervals (1 day to 79 years), with an average of 6.52 years ($SD = 10.81$). The age of the participants at first testing in the studies also ranged widely (1.00–88.50 years), with a mean age of 18.07 years ($SD = 21.37$). The percentage of females in the sample ranged from 0.00% to 100%, with an average of 50.05% ($SD = 23.19\%$). Average general cognitive ability level was available for 456 effect sizes based on 79 samples. These effect sizes indicated an average cognitive ability level of $M = 104.19$ IQ ($SD = 10.37$).

Most of the records included in our meta-analysis were peer-reviewed studies (1,202 effect sizes, 197 samples). The test instruments varied, with the Wechsler tests being the most common (338 effect sizes, 85 samples), followed by the Stanford–Binet test (74 effect sizes, 24 samples). Measurements were predominantly derived from identical tests at both measurement points (751 effect sizes, 172 samples) and from complete tests (928 effect sizes, 161 samples). Furthermore, the majority of studies originated from North America (808 effect sizes, 134 samples) or Europe (420 effect sizes, 62 samples), and only a small minority of studies came from Asia, Africa, or South America (52 effect sizes and 8 samples combined). This indicates that a large majority of studies originated in Western, educated, industrialized, rich, and democratic (WEIRD) societies. The studies span a wide publication period, ranging from 1921 to 2022 ($M = 1998.70$, $SD = 18.64$), reflecting the long-standing interest in this area of research. A closer look at the data reveals that 773 out of 1,288 effect sizes, or approximately 60%, were published after the year 2000, underscoring the growing attention and continued development of this research area over the past 2 decades. Finally, a reliability estimate for the measurements was available for only 250 effect sizes, based on 45 samples. The average reliability was found to be quite high ($\alpha = .89$, $SD = 0.07$), with the low *SD* indicating minimal variation between studies. Reliability was available for at least four samples for each ability, allowing us to conduct robustness checks for the main analyses by controlling for reliability. Nonetheless, this subset of data is considerably less comprehensive and not necessarily representative of the complete data set. Therefore, we subject analyses based on the reliability-adjusted data set to additional scrutiny, comparing the results to those in the same reduced data set without adjusting for reliability (i.e., all effect sizes for which reliability estimates were available).

Supplemental Table S3 presents a correlation matrix of all continuous variables based on the complete data set. Effect sizes (*r*) showed a positive correlation with the participant's age ($r = .42$, $p < .001$) and a negative correlation with both the interval duration ($r = -.22$, $p < .001$) and the year of publication ($r = -.19$, $p < .001$). The number of participants per effect size (*n*) did not show a significant correlation with *r* effect sizes ($r = .05$, $p = .103$) nor with the duration of test–retest intervals ($r = .01$, $p = .779$). Conversely, it showed a positive correlation with the year of publication ($r = .11$, $p < .001$) and negative correlations with sample age ($r = -.08$, $p = .003$), general cognitive ability level ($r = -.15$, $p = .002$), and reliability of measurements ($r = -.14$, $p = .030$). Test–retest interval length was positively correlated with general cognitive ability level ($r = .09$, $p = .048$) and the year of publication ($r = .18$, $p < .001$). Sample age showed a negative relationship with reliability ($r = -.18$, $p < .001$) and a positive relationship with the year of publication ($r = .13$, $p < .001$). General cognitive ability level, the year of publication, and reliability did not show significant

relationships with each other ($p > .05$). Taken together, the correlations indicate that age, test–retest interval, and samples size are associated with various other moderators including sample size and that age and test–retest interval are associated with stability. These results underscore the importance of controlling for the duration of the test–retest interval and sample age, while also considering sample size when conducting moderator analyses for other variables.

Supplemental Table S4 presents a matrix of chi-square tests conducted across all categorical variables based on the complete data set. This additional analysis served to uncover possible confounds of the categorical moderator variables due to uneven distribution of one variable in the categories of another. The chi-square tests revealed that none of the categorical variables demonstrated an even distribution across the other categorical variables. To rule out or examine any confounding influences on the moderator analyses, we conducted an additional review of the significant categorical moderators while controlling for the other significant categorical moderators.

Preanalyses

Outlier Analyses

In the complete data set, 80 effect sizes showed an absolute studentized residual larger than 1.96 and were therefore identified as significant outliers. Cook's distance analyses indicated that 13 of these outlier effect sizes were influential. These effect sizes were noted for robustness check analyses. Four outlier effect sizes were excluded from all further analyses because they constituted negative and therefore implausible rank-order stability coefficients (i.e., Bauer & Smith, 1988, reported an r_{tt} of −.25; Jankowska et al., 2014, reported an r_{tt} of −.51; McArdle & Wang, 2008, reported r_{tt} of −.05 and −.02).

Publication Bias

Funnel plots and trim-and-fill plots based on Fisher's z effect sizes for the complete data set and all subdata sets are presented in Supplemental Figures S1 and S2, respectively (for funnel plots and trim-and-fill plots based on r, see Supplemental Figures S3 and S4). Visually, no extraordinary asymmetry was noted. The trim-and-fill R_0 estimator indicated no significant publication bias in either data set ($p > .05$). Egger's regression analyses indicated significant asymmetry in the complete data set ($z = 2.30$, $p = .021$) and g ($z = 2.01$, $p = .044$) and no significant asymmetry in all other subdata sets ($p > .05$). Two samples causing significant asymmetry in the complete data set and g were noted for robustness check analyses. Finally, publication type was not significantly related with stability in either data set ($p > .05$) and thus indicated no publication bias.

Main Analyses

Hypothesis 1: Test–Retest Interval

Model fit indices for models testing linear, quadratic, and exponential test–retest interval effects on stability are reported in Table 2. In the complete data set, and for g, Gc, and Gv, the exponential test–retest interval function showed the best fit (i.e., lowest BIC). In Ga, Gc, Gl, Grw, Gs, and Gwm, the linear test–retest interval function indicated the best fit. In Gq, the quadratic function indicated the best fit. However, these linear and quadratic trends were based on small data sets ($df < 4$) and therefore cannot be interpreted substantively. Figure 4 depicts the exponential test–retest interval function based on the complete data set. The model parameters of the best-fitting models in all data sets are reported in Table 3 (parameters of the remaining models are reported Supplemental Table S6) and depicted in Supplemental Figure S5. The exponential test–retest interval functions in the complete data set, g, Gc, and Gv, indicate that stability initially steeply decreased with each additional year of the test–retest interval, whereas after approximately 5 years, the stability did not further decrease with increasing duration of the test–retest interval and approximated a fixed asymptote of .69 (complete data set), .67 (g), .73 (Gc), and .66 (Gv).

Hypothesis 2: Age

Model fit indices for models testing different functional forms of the age effects on stability and their interaction with test–retest interval in Steps 1, 2, and 3 are reported in Table 2. In Step 1, the exponential age function showed the best model fit in the complete data set, g, Gc, Gf, Gs, Gv, and Gwm (i.e., lowest BIC). The linear age function indicated the best model fit in Ga, Gl, and Gq. The linear spline function showed the best model fit in Grw.

Figure 5 depicts the exponential age function as well as the linear spline age function based on the complete data set. The model parameters of the best-fitting models are reported in Table 3 (parameters of the remaining models are reported in Supplemental Table S5) and depicted in Supplemental Figure S6. The exponential age functions in the complete data set, g, Gc, Gf, Gs, Gv, and Gwm, indicate that stability initially increased with each additional year of age, whereas after approximately 20 years, the stability did not further increase with increasing age and approximated a fixed asymptote of .79 (complete data set), .84 (g), .85 (Gc), .78 (Gf), .82 (Gs), .79 (Gv), and .76 (Gwm). In Gl and Gq, linear models indicated increasing stability with increasing age over the entire life span. In Ga, the linear distribution could not be interpreted because of too few samples. In Grw, the linear spline function could not be interpreted because $df < 4$.

In the complete data set, the comparison of Step 2 and Step 3 analyses indicated that model fit improved after the additional inclusion of the interaction with test–retest interval duration. This interaction is illustrated in Figure 6, demonstrating that the effects of the test–retest interval are more pronounced in young children compared to adolescents or adults. In all other data sets, the interaction of age with test–retest interval duration did not enhance the model fit. The model parameters of the best-fitting models are reported in Table 3. The parameters of the best-fitting models are presented in Table 3. It is important to note that, with only a few exceptions, the direction and significance of age effects remained consistent, even after controlling for the test–retest interval.

Additional exploratory analyses in a single subsample comprised of preschool children, school-aged children, and adolescents did not

indicate interaction effects of age and test–retest interval (see Supplemental Table S7 for details).

Residualization of Test–Retest and Age Effects Before Conducting Hypotheses 3–10

The best-fitting function in analyses of Hypothesis 2 for the complete data set included exponential effects of test–retest interval and age and their interaction. We used estimates from this model to residualize all effect sizes as follows:

$$\begin{aligned} r_{\text{residualized}} = r_{\text{observed}} &- (.746 - .005e^{-.223 \times \text{age} - .002 \times \text{age} \times \text{interval}} \\ &+ .025\text{e}^{-.265 \times \text{interval}}) \\ &+ (.746 - .005e^{-.223 \times 0 - .002 \times 0 \times 0} \\ &+ .025\text{e}^{-.265 \times 0}). \end{aligned} \quad (7)$$

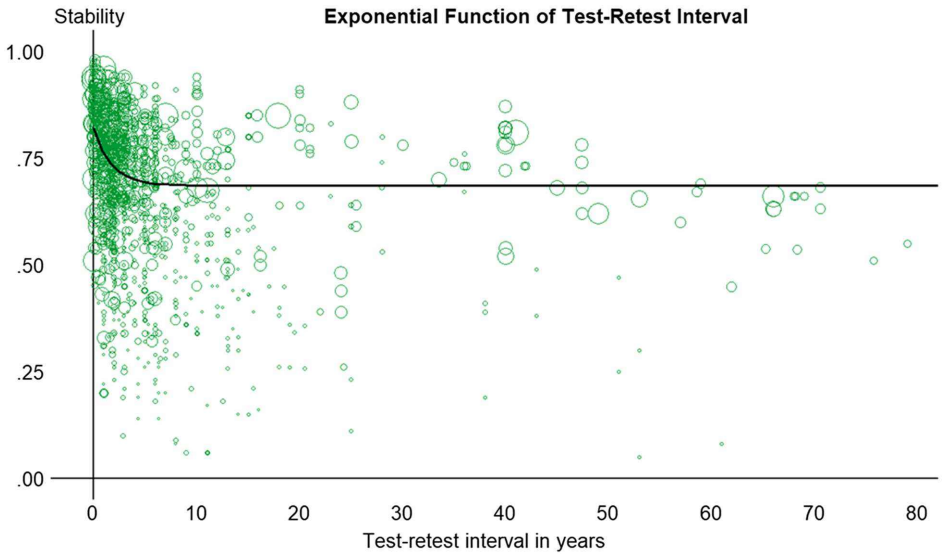
That is, we first subtracted the expected *r* value (i.e., the first bracket) from the observed *r* value (i.e., r_{observed}) to get the deviation from the expected value at a given interval and age. We then added the expected *r* value at interval = 0 and age = 0 (i.e., the second bracket) to this deviation. Thus, $r_{\text{residualized}}$ reflects the *r* value which we predicted according to our statistical model for r_{observed} at interval = 0 and age = 0. Note that interval = 0 represents the interval of 5 years and age = 0 represents the age of 20 years because 5 and 20 were subtracted from the interval and age variables, respectively, before we conducted these analyses. By applying this formula, each effect size was transformed into a corresponding model implied effect size for age 20 with a test–retest interval of 5 years.

Hypothesis 3: Magnitudes of Rank-Order Stabilities

Table 4 reports the magnitudes of rank-order stabilities at the age of 20 years and a test–retest interval of 5 years, as implied by the best-fitting model for each data set. Estimates ranged from ρ = .65 in Ga to ρ = .80 in *g*. The mean effect across all abilities was ρ = .76. The robustness checks indicated no noticeable differences from the main analyses (see Supplemental Table S10).

Figure 4

Rank-Order Stability as an Exponential Function of Test–Retest Interval Based on the Complete Data Set



Note. Larger points represent larger weight of the effect sizes. See the online article for the color version of this figure.

Hypothesis 4: Cognitive Ability Captured

The captured cognitive ability significantly moderated stability. We found a significantly lower stability in Ga ($\rho = -.15$, $p = .043$), Gf ($\rho = -.11$, $p < .001$), Gs ($\rho = -.05$, $p = .018$), Gv ($\rho = -.05$, $p = .007$), and Gwm ($\rho = -.13$, $p = .002$) than in the reference category *g*, whereas Gc and Gq did not significantly differ from *g* ($p > .05$; for more details, see Table 3).

Hypothesis 5: General Cognitive Ability Level

The general cognitive ability level of the sample was not significantly related to stability in any data set ($p > .05$; for more details, see Table 3). For some abilities, the analyses were not conducted or could not be interpreted because of too few samples.

Hypothesis 6: Test Instrument

In the complete data set and the subdata sets of *g*, Gf, and Gv, the test instrument significantly moderated stability, whereas it was not related to stability in the subdata sets of Gc, Gq, Gs, and Gwm ($p > .05$; for more details, see Table 3). In Ga and Gl, these analyses were not conducted because of too few samples. In the complete data set, CFT ($\rho = -.09$, $p = .019$), Raven's matrices ($\rho = -.17$, $p < .001$), Woodcock–Johnson ($\rho = -.08$, $p = .004$), and mixed instruments ($\rho = -.04$, $p = .044$) demonstrated significantly lower stability than the reference category WISC. In *g*, Woodcock–Johnson ($\rho = -.08$, $p = .004$) had a significantly lower stability than the reference category WISC. In Gf, CFT ($\rho = .09$, $p = .034$), other instruments ($\rho = .13$, $p = .003$), and mixed instruments ($\rho = .16$, $p < .001$) demonstrated a higher stability than the reference category Raven's matrices. In Gv, Woodcock–Johnson ($\rho = -.10$, $p = .036$) and the other instruments category ($\rho = -.10$, $p = .031$) showed significantly lower stabilities than the reference category WISC.

Hypothesis 7: Varying Measurement Instruments

In the complete data set, *g*, Gc, Gf, and Gwm varying measurement instruments significantly moderated stability. The use of different tests at the two times of measurement was associated with a lower stability compared to the reference category same test. In Ga, Gl, Gq, Grw, Gs, and Gv, these analyses were not conducted or interpreted because of too few samples.

Hypothesis 8: Complete Test

In the complete data set and *g*, incomplete testing was associated with lower stability than the reference category complete testing (complete data set: $\rho = -.04$, $p = .009$; *g*: $\rho = -.04$, $p = .034$; for more details, see Table 3). In Gc, Gf, Gq, Gs, Gv, and Gwm, incomplete testing was not significantly related to stability. In Ga, Gl, and Grw, these analyses were not conducted because of too few samples.

Hypothesis 9: Geographic Location

In the complete data set and *g*, we found a slightly lower stability in Europe than in the reference category North America (complete data set: $\rho = -.05$, $p = .002$; *g*: $\rho = -.05$, $p = .024$; for more details, see Table 3). In Gc, Gf, Gq, Gs, and Gv, geographic location was not

Table 3
Moderator Analyses of Rank-Order Stability in Cognitive Ability

Data set	Predictor	Reference category	ρ	*df*	*p*	95% confidence interval	I^2	τ^2

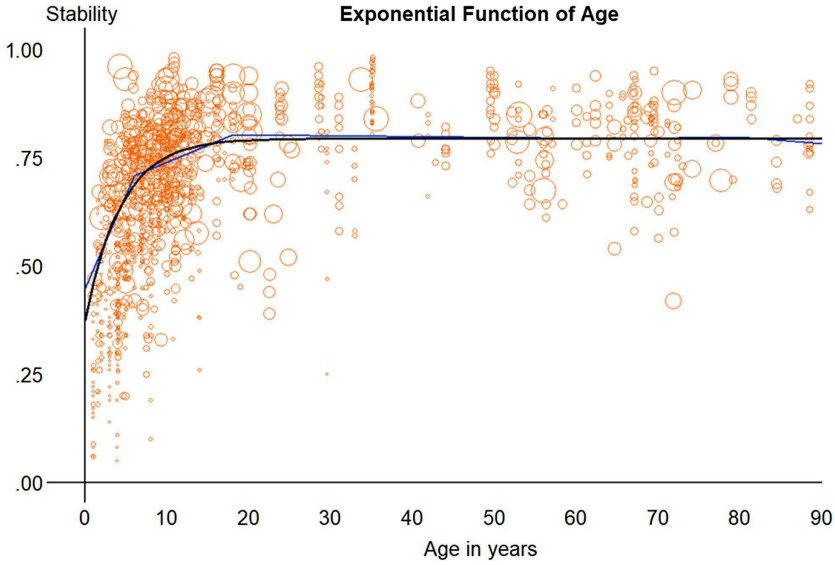
Note. Complete = complete data set including *g* and CHC broad abilities. As we subtracted 5 from the test–retest interval, the intercepts in models including test–retest interval represented a 5-year interval instead of a 0-year interval. As we subtracted 20 from the age, the intercepts in models including age represented a 20-year age instead of a 0-year age. ρ = effect size; *df* = degrees of freedom; H = Hypothesis; CFT = Culture Fair Test; WISC = Wechsler Intelligence Scale for Children; CHC = Cattell–Horn–Carroll model of cognitive ability.

Figure 5

Rank-Order Stability as Exponential (Black) and Connected Linear Spline (Blue) Functions of Age Based on the Complete Data Set



Note. Larger points represent larger weight of the effect sizes. As reported in Supplemental Table S2, the mean test–retest interval was 6.52 years. See the online article for the color version of this figure.

significantly related to stability. In Ga, Gl, and Grw, these analyses were not conducted because of too few samples.

Hypothesis 10: Using Reliability Estimates to Disattenuate for Measurement Error

Exponential age effects were confirmed in the subset of effect sizes with available reliability information (see Table 3 and Figure 7). Both the model unadjusted for reliability and the model adjusted for reliability demonstrated that stability initially increased with each additional year of age, whereas after approximately 20 years, the stability did not further increase with additional aging. The two models only substantially differed in the fixed asymptote that was reached after approximately 20 years (unadjusted for reliability: asymptote = .80, $p < .001$; adjusted for reliability: asymptote = .90, $p < .001$). The age scaling factor and growth rate were almost identical in both models (for more details, see Table 3).

In the model not adjusted for reliability, the stability estimates for the different cognitive abilities were nearly identical to the analysis based on all effect sizes. The most significant difference was found in Gl (all effect sizes: $\rho = .69$, $p < .001$; only effect sizes with available reliability information: $\rho = .64$, $p < .001$). Thus, the subset of effect sizes with available reliability information appears representative of the complete data set in terms of stability. The estimates of stability in the model adjusted for reliability were substantially higher than those unadjusted for reliability, with ρ differences ranging from $\rho = .06$ in Gl to $\rho = .11$ in Gv (for more details, see Table 3). Therefore, as expected, not accounting for reliability leads to an underestimation of the stability of cognitive abilities.

In the moderator analysis of cognitive ability captured, a slightly different pattern emerged after adjusting for reliability compared to the complete, unadjusted data set, particularly regarding Gf, Gs, and Gwm (see Table 3). Without adjusting for reliability, significant negative effects were observed for Gf ($\rho = -.12$, $p = .001$), Gs ($\rho = -.09$, $p = .023$), and Gwm ($\rho = -.18$, $p = .033$) indicating lower stability compared to general intelligence. Yet, after adjusting for reliability, these effects were no longer statistically significant: Gf ($\rho = -.07$, $p = .055$), Gs ($\rho = -.06$, $p = .200$), and Gwm ($\rho = -.17$, $p = .073$). It is important to note that despite these changes in statistical significance, the descriptive values remained negative, though to a lesser extent, even after adjusting for reliability.

The moderator analysis for the test instrument also showed substantial shifts when adjusting for reliability (see Table 3). In the model without adjusting for reliability, the Woodcock–Johnson test showed significantly negative effects compared to the Wechsler test, with $\rho = -.07$ ($p = .045$). Yet, after adjusting for reliability, this effect, although they remained negative, did not reach statistical significance ($\rho = -.06$, $p = .109$). This finding supports the assumption that the observed different stabilities of the tests can be explained by differences in their reliability.

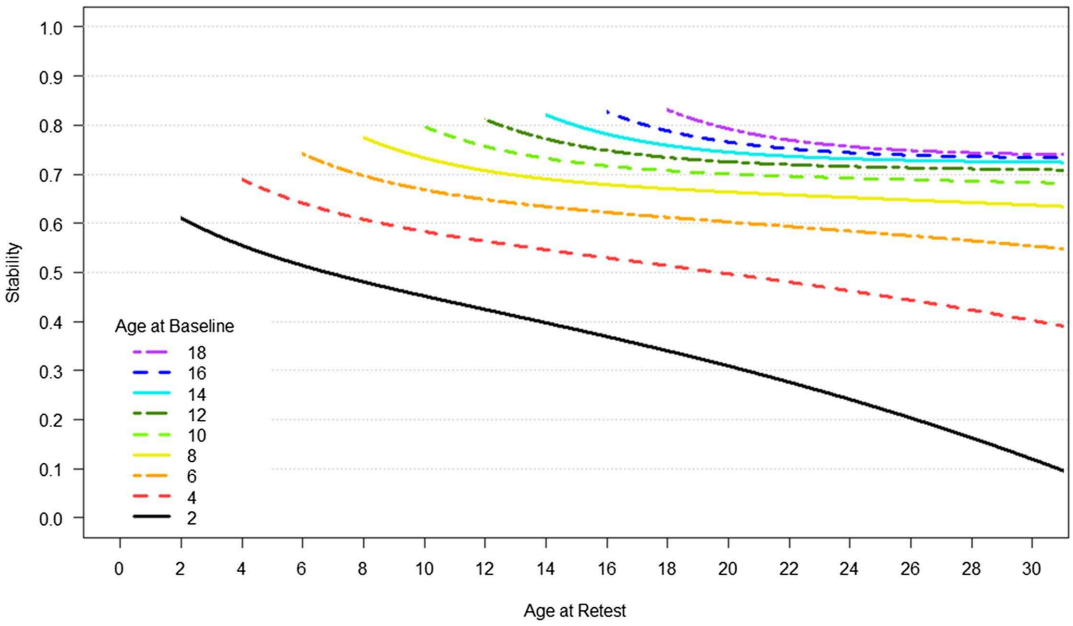
Exploratory Sensitivity Analyses

Simultaneous Inclusion of All Categorical Moderators

In the comprehensive model that simultaneously included all categorical moderators, the effects of captured cognitive ability showed minimal variation from the initial analyses, except for Ga, which did not retain its statistical significance. Certain effects of test instruments demonstrated shifts in statistical significance within this comprehensive model. Notably, the CFT and Woodcock–Johnson tests did not retain their initial significant difference from the Wechsler test, while the effect sizes for Raven's Progressive Matrices remained relatively consistent. This finding can be partly

Figure 6

Temporal Decay of Stability of Cognitive Abilities in Childhood and Adolescence Based on the Exponential Age and Interval Moderator Functions



Note. Each plotted line represents a different baseline age followed with increasing time lags. See the online article for the color version of this figure.

attributed to the fact that CFT tests (37 out of 37 effect sizes, 100%) are used for the assessment of Gf, which showed significantly lower stability than *g* in the initial analyses. Furthermore, in all instances (57 out of 57 effect sizes, 100%), the Woodcock–Johnson test scales were utilized incompletely, which generally demonstrates lower stability than complete tests. The comprehensive model confirmed that using different tests leads to lower stability compared to using the same test, while the effect of using tests from the same test family remained statistically nonsignificant. The effects of incomplete tests versus complete tests lost significance in the comprehensive model, which can be attributed to the inclusion of all Woodcock–Johnson assessments (57 out of 57 effect sizes, 100%). Last, the effect of European samples showing less stability compared to North American samples was not maintained in the comprehensive model. This shift can be partly attributed to the fact that a majority of Raven assessments (25 out of 41 effect sizes, 61%) were conducted with European samples and that European effect sizes more often referred to incomplete assessments (147 out of 418 effect sizes, 35% in Europe vs. 186 out of 808 effect sizes, 23% in North America).

Table 4

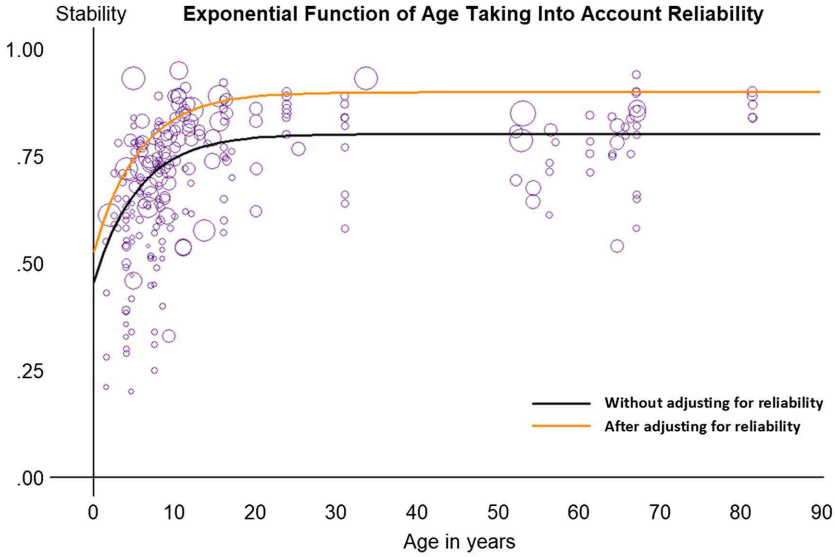
Magnitude of Rank-Order Stability in Cognitive Ability for a Sample Age of 20 Years and a Test–Retest Interval of 5 Years

Data set	Predictor	ρ	*df*	*p*	95% CI	I^2	τ^2
H3: Magnitude of ρ							
Complete	Intercept	.762	197.665	<.001	[.748, .776]	98.661	.015
g	Intercept	.801	142.932	<.001	[.786, .817]	98.738	.010
Ga	Intercept	.651	3.996	<.001	[.512, .789]	90.373	.013
Gc	Intercept	.791	67.290	<.001	[.766, .816]	94.154	.003
Gf	Intercept	.708	56.745	<.001	[.680, .735]	95.602	.012
Gl	Intercept	.688	6.990	<.001	[.591, .786]	95.529	.025
Gq	Intercept	.770	10.005	<.001	[.711, .829]	93.647	.004
Grw	Intercept	.776	5.897	<.001	[.636, .915]	96.280	.008
Gs	Intercept	.738	24.135	<.001	[.694, .781]	92.028	.008
Gv	Intercept	.747	55.570	<.001	[.719, .775]	90.031	.009
Gwm	Intercept	.687	20.871	<.001	[.636, .739]	87.504	.009

Note. Parameters were estimated based on random-effects intercept-only models. Prior to the analyses, test–retest and age effects were residualized out from the effect sizes. Therefore, in each model, the intercept can be interpreted as the magnitude of rank-order stability for a sample age of 20 years and a test–retest interval of 5 years. Complete = complete data set including *g* and CHC broad abilities. ρ = effect size; *df* = degrees of freedom; CI = confidence interval; CHC = Cattell–Horn–Carroll model of cognitive ability.

Figure 7

Rank-Order Stability as an Exponential Function of Test–Retest Interval Based on Effect Sizes for Which Reliability Information Was Available



Note. Larger points represent larger weight of the effect sizes. Depicted points represent unadjusted effect sizes. See the online article for the color version of this figure.

Age Analysis Based on Age-Homogeneous Samples

The exponential age model based on age-homogeneous samples ($SD < 5$ years) revealed stability parameters and age effects that were nearly identical to those in the complete data set (for more details, see Table 3). This finding implies that the inclusion of age-heterogeneous samples did not significantly distort the results of the age analyses performed in Hypothesis 2.

Discussion

The present study provides the first comprehensive meta-analysis on the stability of cognitive ability over the life span. We investigated the rank-order correlations of cognitive abilities and their moderators in 205 samples. The analyses were conducted on the overall data set as well as on subdata sets pertaining to general intelligence and broad cognitive abilities, thereby covering the top two strata of the CHC model, the most recent psychometric model of cognitive ability.

Overall, cognitive abilities were exceedingly stable over considerable time spans, with stabilities ranging from .65 to .80 for a 5-year interval and an age of 20 depending on the specific ability. The highest stability was observed for general intelligence. Interestingly, the more knowledge-based abilities of comprehension knowledge, quantitative knowledge, and reading and writing were similarly stable to general intelligence. In contrast, abilities that are based on effortful processing, such as fluid reasoning, learning efficiency, or working memory capacity, tended to exhibit lower stabilities. This finding may seem counterintuitive, as effortful processing-based abilities are usually thought to be less dependent on environmental influences (e.g., Baltes et al., 1999) and therefore less susceptible to environmental changes. On the other hand, in a somewhat different argument, Tucker-Drob and Briley (2014) hypothesized that environmental experiences relevant to knowledge-based abilities may produce lasting stores of declarative knowledge. A similar argument can be made from the perspective of investment theory (Cattell, 1986). This theory proposes that during cognitive development, fluid (or effortful processing–based) abilities are invested in the acquisition of crystallized (or knowledge-based) abilities. As the result of years of cumulative investment, these crystallized abilities are acquired and automated, such that they are better maintained even as currently available processing power wanes with aging (see also Baltes et al., 1999) or varies from day to day. Indeed, effortful processing abilities are known to begin to decline at much earlier periods in adulthood than are knowledge-based abilities (Baltes et al., 1999; Tucker-Drob, 2019). Heterogeneity in trajectories of the aging of processing abilities at earlier period of adulthood may contribute to their lower overall stability as compared to knowledge-based abilities (also see Tucker-Drob et al., 2022).

We observed that the differences in stability across abilities are diminished when test reliability is adjusted. This finding implies that the differences are at least partially due to tests of knowledge-based abilities being more reliable than tests of effortful processing–based abilities. This difference in reliability may be due to a potentially lower emphasis on speededness in knowledge tests compared to processing-based tests, which often have strict time limits that can attenuate reliability (Hong & Cheng, 2019). Of course, other test properties such as the average test length or item difficulty distribution may also contribute to systematic differences in the reliability of knowledge-based and effortful processing–based tests.

Moderators

Test–Retest Interval

As expected, stability declined with increasing test–retest intervals, and this decay leveled off with increasing intervals. This trajectory was best described by an exponential function in those data sets that included enough long-interval effect sizes, namely the overall data set, general intelligence, comprehension knowledge, and visual processing. For all other abilities, there were no or very few effect sizes with very long test–retest intervals, which make the resulting curve trajectories difficult to interpret and less trustworthy. The exponential trend is consistent with the results of previous meta-analytic investigations (Schuerger & Witt, 1989; Tucker-Drob & Briley, 2014).

There was evidence for a small but significant interaction effect between age and test–retest interval. This interaction effect implies that the impact of test–retest interval is larger in young children than in adolescents or adults. In 2-year-olds, an increase of test–retest interval from 1 to 5 years results in a decrease in stability by .08. In 5-year-olds, the same increase in interval results in a decrease in stability by .06. From the age of 8 onward, there is little additional change, with an increase of test–retest interval from 1 to 5 years resulting in a decrease in stability by .05. This interaction is in line with the early findings by Bayley (1949) who observed steeper declines in stability with increasing test–retest intervals in younger children than in adolescents. As can be seen in Figure 6, the interaction further implies that until the age of 8, the interval effect is not asymptotic like in adolescents and adults but instead continuously decreasing, especially in very young children.

Age

As hypothesized, stability increased with age and most markedly in early childhood, with the increase leveling off over the course of adolescence until no further increase was observable in adulthood. This pattern is consistent with the results by Tucker-Drob and Briley (2014), whereas the models by Schuerger and Witt (1989) implied a further increase in stability until late adulthood (Figure 2). An exponential curve best described the age trajectories of stability for the complete data set and for all CHC abilities except auditory processing, learning efficiency, and reading and writing where the effect sizes were lacking for older samples and exponential models often did not converge.

Stability was very high in old age (asymptoting at .77 in the complete data set), and there was little evidence for a decrease in stability in late adulthood, implying that cognitive change does not appear to be more heterogeneous in late adulthood than in early and middle adulthood. A high degree of stability in cognitive ability into late adulthood has theoretical implications as it suggests that the same factors or developmental mechanisms may play a role in cognitive decline that previously influenced individual differences in cognitive abilities. For example, the prefrontal cortex, which is associated with executive functions and working memory, may be a central determinant of both cognitive ability in adolescence and adulthood (Kane & Engle, 2002) and cognitive decline in late adulthood (Nyberg et al., 2022). Environmental selection processes may also play a role, leading individuals to remain in similarly cognitively challenging living environments throughout their lives (Harden et al., 2007; van der Sluis et al., 2008), which can also affect cognitive decline (e.g., Frick & Benoit, 2010). Importantly, the studies meta-analyzed were composed of individuals from the general population, and we excluded studies focusing on clinical samples. Studies of older adults in the general population also tend to exclude individuals with mild cognitive impairment and dementia. Moreover, individuals with mild cognitive impairment and dementia are more likely to drop out of longitudinal studies compared to those experiencing milder trajectories of cognitive decline. Thus, it is likely that the full range of heterogeneity in aging-related trajectories among older adults was restricted in many of the studies composing the meta-analytic data set. It remains an open question whether, in a fully representative study of cognitive aging, stability would begin to decrease in old age, as sizable proportions of individuals undergo precipitous declines toward impaired levels of cognitive functioning (Lövdén et al., 2005; Tucker-Drob, 2019).

Interestingly, age trends in stability were very similar for both comprehension knowledge (which shows little decline or even mean-level gains over the course of adulthood) and processing-based abilities such as fluid reasoning and visual processing (which start to decline in early adulthood; Baltes et al., 1999; Tucker-Drob, 2019). Given the different mean-level trajectories over the life span, one might also expect different mechanisms of cognitive change and thus different patterns of reordering between these abilities. Yet, a recent study showed that changes in knowledge-based and processing-based abilities are correlated over the life span: Individuals who experience a greater decline in processing-based abilities also experience smaller gains or even a decline in knowledge-based abilities (Tucker-Drob et al., 2022). This finding implies that the same underlying mechanisms drive change in all cognitive abilities (see also Li et al., 2004) or that the underlying mechanisms are closely related, which is consistent with the present observation of similar stability patterns over the life span in all abilities. Of course, even if all long-term cognitive changes in adulthood are driven by the same mechanisms, there may be differences between specific abilities in their susceptibility to change by shorter term environmental influences.

General Cognitive Ability Level

The effect of the cognitive ability level of the sample on stability could only be investigated for some abilities because of insufficient data in the others. In both the overall data set and the individual abilities where the analysis was possible, including general intelligence, there was no significant effect of mean cognitive ability level on stability. This finding is somewhat inconsistent with predictions based on the ability differentiation hypothesis. As the ability differentiation hypothesis states that general intelligence accounts for less systematic variance of cognitive performances in high-ability individuals, it would predict that the stability of composite measures of general intelligence decreases with increasing ability level (e.g., Breit, Brunner, et al., 2022). The absence of this effect may be due to the ability differentiation effect being not very consistent in children (Breit, Brunner, et al., 2021), and given the large number of studies based on samples of children in the present meta-analysis, this may significantly reduce the overall impact of the ability differentiation effect. Even more importantly, the impact of the ability differentiation effect may also not be particularly evident in meta-analytic investigations because the variance of cognitive ability within samples is much larger

than that between samples. The ability differentiation effect implies rather large differences in *g*-factor variance between the average and the very high or very low regions of the ability distribution but small differences within a few IQ points around the population average (Breit, Brunner, et al., 2022). Nevertheless, in the present analysis, there is no evidence for the hypothesized effect of ability level—and therefore of ability differentiation—on the stability of general intelligence.

Test Instruments

The effect of the test instrument was investigated across three moderator analyses. The results were consistent with our hypotheses. When the same test or tests from the same test family were used at both times of assessment, this led to greater stability estimates than when the test instrument changed between test and retest. This difference remained in the analysis that included all categorical moderators. Moreover, using complete test batteries led to greater stability than using only a selection of subtests from one or several test batteries. We also found that unidimensional tests such as the Raven tests displayed less stability than the Wechsler tests, whereas other multidimensional tests such as the Stanford–Binet tests were comparable to the Wechsler tests in stability. The only exception to this rule was the Woodcock–Johnson test, which displayed lower stability than the Wechsler tests, but was never used completely. Taken together, the highest stability would be expected if the same multidimensional intelligence test was used in its entirety at both times of measurement. Multidimensional tests are usually more reliable than unidimensional tests due to their greater length, and longer test forms (e.g., complete tests) are more reliable than short forms (e.g., a selection of subtests). We found that when adjusting for test reliability, the differences in stability between tests were diminished indicating that stability differences between tests can largely be explained by test reliability.

When different tests are used at different times of measurement, the stability is further limited by the magnitude of the concurrent correlation between the different tests (which cannot be exceeded by the test–retest correlation). In addition, memory effects could contribute to the higher stability when the same test is used at both times of measurement. When interpreting these findings, however, it must be kept in mind that unidimensional tests generally measure fluid reasoning, which shows less stability than knowledge-based abilities. Thus, it cannot be completely ruled out that the lower stability of unidimensional procedures is partly or completely due to the lower stability of fluid reasoning. Looking at the comparison only within fluid reasoning, Raven's matrices are descriptively less stable than multidimensional tests, but not significantly so.

Geographic Location

The last investigated moderator was the geographic origin of the sample. The number of samples for each continent only allowed the comparison between North America and Europe. The stability was generally higher in North American samples, which was statistically significant in the full data set and general intelligence. One explanation is that studies based on North American samples may on average use more stable test instruments than studies based on European samples. Indeed, in the analysis including all categorical moderators, the difference between Europe and North America no longer reached statistical significance.

Adjusting for Reliability

A subset of effect sizes was reanalyzed while adjusting for test reliability. Three main findings emerged from these analyses. First, the mean stability estimate for age 20 and a test–retest interval of 5 years increased from $\rho = .76$ in the full, unadjusted, data set to $\rho = .86$ for the disattenuated correlations. This value suggests that even when adjusting for reliability in adults, cognitive abilities are not perfectly stable, although the stability is very high. Second, the age moderation curve was mostly unaffected by reliability. The low stability in young children does not appear to be primarily due to lower test reliability in this age group. This may seem surprising, as one might expect lower test reliability in young children, given that cognitive testing is more challenging in this age group, but this problem is usually compensated for by individual testing with extensive, age-appropriate test batteries. Conversely, in adults, researchers often rely on shorter scales, sometimes administered in group settings. This practice might explain the overall low correlation between test reliability and mean sample age ($r = .05$). Third, the differences in stability between knowledge-based and effortful processing–based abilities diminished when adjusting for reliability. While the difference in stability between general intelligence and comprehension knowledge and reading and writing was largely unaffected by adjusting for reliability, the difference between general intelligence and fluid reasoning decreased from $-.12$ to $-.07$. Similar reductions were observed for processing speed and visual processing. Thus, reliability differences between tests of knowledge-based and effortful processing–based abilities in part account for the tests' differences in stability.

The Stability of Cognitive Abilities in Comparison to Other Constructs

Similar meta-analyses to the present one have been conducted for other personality constructs. Six major meta-analyses on various constructs and the present meta-analysis are summarized in Table 5. The mean time intervals in these meta-analyses ($Mdn = 4.88$ years, range = 1.65–7.06 years) were comparable to the chosen reference interval in the present meta-analysis (5 years). The stability of cognitive abilities was generally higher than that of Big Five personality traits, self-esteem, vocational interests, work values, and motivational constructs. One notable exception was the stability of work values in 25- to 30-year-olds ($\rho = .83$). Yet, this specific estimate was based on only two effects and can therefore not be regarded as reliable.

The age moderation of the stability of cognitive abilities implied a strong increase in stability over the course of childhood and adolescence, leveling off around age 18, with stability remaining constant in adulthood. The stability of personality traits increases with age not only during childhood and adolescence but also into adulthood until the age of 50 (Roberts & DelVecchio, 2000), although there appears to be some heterogeneity between traits (Bleidorn et al., 2022). Both vocational interests and self-esteem also increased in stability during childhood and adolescence, but the stability decreased again after early adulthood (Low et al., 2005; Trzesniewski et al., 2003). Last, no systematic age trend was

Table 5
Comprehensive Meta-Analyses on the Rank-Order Stability of Psychological Constructs

Reference	Construct	ρ	*h*	M_{age} in years	*M* interval in years	Statistically significant moderators
Roberts and DelVecchio (2000)	Personality traits	.35–.75[a]	175	17.84	6.75	Age, interval, type of trait
Trzesniewski et al. (2003)	Self-esteem	.50	168	14.00	4.90	Age, interval, year of assessment

observable in the stability of work values (Jin & Rounds, 2012), but this meta-analysis did not include studies with samples of young children. Taken together, stability generally increased during childhood and adolescence across all constructs. Differences between constructs were observable in adulthood, with constancy of stability in cognitive abilities and work values, decrease of stability in vocational interests and self-esteem after early adulthood, and a further increase in personality traits until middle adulthood.

The overall higher stability of cognitive ability compared to the other constructs suggests that cognitive ability may be a more trait-like construct, particularly in adolescence and adulthood, whereas many other psychological constructs may be somewhat more state-like construct (Geiser et al., 2017). State-like constructs have been conceptualized as being more immediately responsive to—potentially fluctuating—contexts and experiences (e.g., Conley, 1984), whereas trait-like constructs have been conceptualized as relatively stable and more slowly changing (Nesselroade & Liben, 1991). Genetic contributions to both cognitive abilities and personality are especially stable from middle to late adulthood (Briley & Tucker-Drob, 2017; Tucker-Drob & Briley, 2014). The particularly high heritability of cognitive abilities in adulthood may help to account for its higher overall stability during this period (Tucker-Drob & Briley, 2014). Of course genetic influences on cognitive abilities are likely to be contingent on environmental contexts (Tucker-Drob et al., 2013), and there is strong evidence that a multitude of environmental factors, such as educational attainment, also contribute to lifelong cognitive function (Lövdén et al., 2020; Ritchie & Tucker-Drob, 2018).

Differential developmental trends in stability of different psychological constructs may be explained by influences specific to those constructs. Personality traits are hypothesized to reach peak stability with the highest levels of identity certainty in life, which is around middle age (Bleidorn et al., 2022; Roberts & DelVecchio, 2000). Conversely, self-esteem was suggested to undergo changes later in life when individuals review their accomplishments and experiences (Trzesniewski et al., 2003), whereas the stability of vocational interest may change depending on the educational or professional stage the individual is in (Low et al., 2005). The relatively constant high levels of stability of cognitive abilities throughout adulthood suggest that cognitive abilities are either relatively unaffected by such life events or that the events and contexts relevant for adult cognitive function are highly stable over time or correlated with one another over time.

Implications for Applied Assessment and Longitudinal Research

The findings on the age and interval dependence of stability have important implications for cognitive ability testing practice. Testing is often done to inform treatment and intervention decisions or to provide guidance regarding educational or vocational decisions. These applications often presume that the relevant cognitive functions are either stable over the intervention window or period of time relevant to the educational or vocational decision or that they would have otherwise been stable absent the intervention (Cronbach & Snow, 1977). There are no clear conventions regarding the minimum level of stability needed, but it has been suggested that a stability of .70 may be sufficient for group decisions, whereas a stability of at least .80 should be required for individual diagnostic decisions (Watkins & Smith, 2013). The best-fitting curves for describing the

age and interval moderation of the stability of cognitive abilities determined in the present analyses make it possible to calculate for each age the maximum time interval for which these specific stabilities can still be expected. Using these curves, we may estimate the ages at which a certain rank-order stability of test scores of cognitive abilities may be achievable, along with the corresponding time interval beyond which a retest is warranted because sufficient stability can no longer be assumed. It should be noted, of course, that rank-order stability is not an individual-level metric. Even high rank-order stability does not preclude the possibility of large changes in intelligence over short intervals for specific individuals. Especially in circumstances of serious illness, neurological trauma, psychosocial stress, or dramatic changes in educational or social experiences, shorter retest intervals may be warranted than would be recommended based on the results of the present meta-analysis. Importantly, however, the decision to reassess individuals frequently, or over short retest intervals, must pay particular attention to validity threats associated with retest effects (Salthouse & Tucker-Drob, 2008).

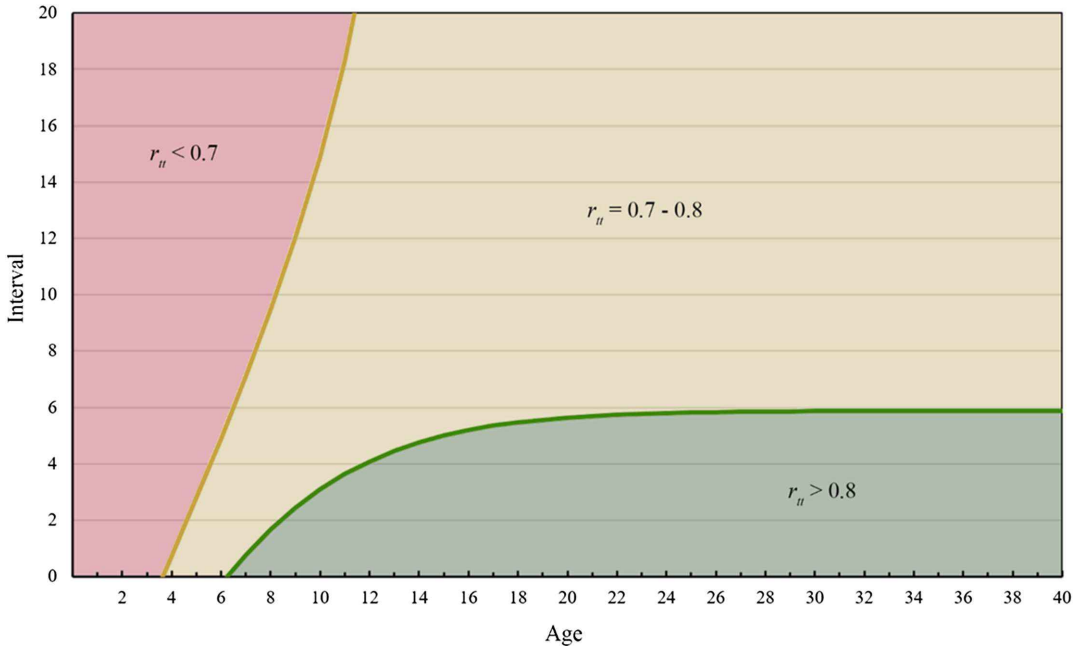
We provide estimates for general intelligence stability thresholds based on the age and interval moderator analyses (see Supplemental Material for computational details). Figure 8 presents the maximum test–retest interval for which the stability criteria of .70 and .80 can still be satisfied, depending on the age of the tested person. When applying a strict criterion of at least $r_{tt} = .80$ as suitable for individual-level decisions, this stability is not obtained in children younger than 6 years old. In 8-year-olds, this stability can be assumed for almost 2 years; in 12-year-olds, it can already be assumed for approximately 4 years. At age 18 and beyond, a stability of .80 can generally be assumed for approximately 6 years, after which retesting would be recommended. When applying a more liberal criterion of $r_{tt} = .70$ that may be suitable for group-level decisions, this stability can already be obtained starting at age 4. The maximum interval for this stability increases rapidly with age, reaching 5 years at age 6, 12 years at age 9, and 18 years at age 11. After the age of 14, $r_{tt} > .70$ stability can be assumed for the full life span.

The resulting curves divide the age interval space into three zones. In the leftmost zone, beyond the .70 line, adequate stability cannot be expected. This zone mainly concerns children under 4 years of age as well as children and adolescents between 4 and 18 years of age in the case of excessively long intervals. In the middle zone between the two lines, only moderate stability can be assumed. This zone concerns children under 7 years of age, children and adolescents with medium length to long intervals (increasing strongly with age), and adults with time intervals longer than 6 years. Last, in the bottom right zone, high stability can be assumed. It should be noted that the .70 and .80 values delimiting these zones are chosen somewhat arbitrarily, they present minimum values, and other values could be selected based on the specific question or application context.

The interval estimations may also be used in the planning of longitudinal studies. Cognitive abilities are often used as control variables or predictors of performance, achievement, or motivation. The present results can be used to determine when or how often cognitive abilities are to be measured to obtain results that are still relevant at the time of testing other variables. For example, school achievement at age 16 may be predicted by general intelligence. The results suggest that general intelligence measures as early as age 11

Figure 8

Maximum Intervals (in Years) for Which a Stability of .70 and .80 Is Obtained for Measures of General Intelligence, as Implied by the Age and Interval Duration Moderator Analyses of General Cognitive Ability (Exponential Models)



Note. See the online article for the color version of this figure.

can still be regarded as very relevant due to a stability above .80. Measurements between the ages of 8 and 10 are still somewhat relevant (i.e., stability >.70), whereas measurements from age 7 or below are not stable above .70 until age 16.

A second and related implication concerns the differences in stability between general intelligence and specific ability scores. Previous studies have sometimes found a large discrepancy between a very stable general intelligence score and much less stable specific ability scores, calling into question the diagnostic utility of the latter (e.g., Ryan et al., 2010; Watkins & Smith, 2013). Our results provide only partial support for this notion. Specifically, we found that knowledge-based abilities were comparably stable to general intelligence, suggesting that their relative diagnostic utility is not particularly limited by their stability. Conversely, scores relating to effortful processing abilities may sometimes be insufficiently stable to support diagnostic decisions with long-term consequences, especially in young children, where stability is generally lower. We observed particularly low stabilities in learning efficiency and working memory, the latter even when adjusting for test reliability. Thus, special caution seems warranted if these scores are to be used as the basis of interventions or counseling.

A third implication of the present results is based on the finding that multidimensional cognitive ability tests such as the Wechsler and Stanford–Binet tests have a higher stability than unidimensional tests such as CFT or Raven tests. Thus, when making decisions with long-term consequences, multidimensional test batteries may be preferred. Of course, unidimensional tests have advantages, such as shorter test times, specificity of information about individual domains of functioning, and the capability to assess many abilities nonverbally. In practice, these advantages must be weighed against the disadvantage of lower stability. It should be noted that the lower stability of effortful processing–based abilities compared to knowledge-based abilities may be at least partly responsible for the lower stability of unidimensional tests as the unidimensional tests in this meta-analysis were classified as fluid reasoning tests. More frequent retesting may generally be necessary for effortful processing–based abilities. Of course, retest effects need to be taken into account when planning repeated testing, especially when using the same test instrument (Hausknecht et al., 2007; Salthouse & Tucker-Drob, 2008; Scharfen et al., 2018). There is some evidence that when using the same test instrument for test and retest, interval durations of at least 2 years are required to reduce the retest effects to the level of retest effects with different test instruments (Hausknecht et al., 2007), but retest effects have also been detected in longitudinal studies after periods of 7 years or more (Horn & Donaldson, 1976; Salthouse et al., 2004; Thorvaldsson et al., 2006).

Remaining Gaps in Our Knowledge About the Stability of Cognitive Abilities

In the present meta-analysis, we were able to draw on a very broad evidence base, covering a wide age range, very short to extremely long test–retest intervals, and many different cognitive abilities and tests of cognitive ability. The large number of studies and their heterogeneity along these dimensions allow for a deeper understanding of the stability of cognitive ability. Still, the evidence base is also limited in several ways.

First, effect sizes are not evenly distributed across age groups. In general, there are fewer studies with adult samples than with children and adolescents, especially between the ages of 30 and 50 and over 70. More data from older adults in particular would be helpful to improve our understanding of cognitive aging. The current results suggest that stability remains very high even in the oldest adults, but more research is needed to confirm this finding and to investigate possible moderators. Importantly, we did not include studies from clinical populations, and longitudinal studies of nonclinical populations (of the sort included in the current meta-analysis) typically exclude individuals with conditions that may interfere with cognitive function (e.g., those with dementia). It may be the case that the stability of cognitive function decreases as the prevalence of such conditions increases with advancing old age. Longitudinal research taking an inclusive approach to following individuals over time, regardless of the incidence of disorders of aging, would be needed to empirically test this hypothesis.

Second, studies have predominantly been conducted with WEIRD samples. WEIRD samples are in many ways unrepresentative of humanity as a whole (Henrich et al., 2010; Nielsen et al., 2017). The search was limited to English reports, was conducted in English, and was conducted in predominantly English databases. This reduced the likelihood of finding and including appropriate studies from non-WEIRD samples, contributing to the somewhat biased study selection. More data from other cultural backgrounds are needed to understand the impact of cultural, economic, and educational factors on the stability of cognitive abilities. There is some tentative evidence for the generalizability of factor analytic models of intelligence across cultures (Wilson et al., 2023), but it is unclear to what extent other properties observed in WEIRD samples, such as high stability, are universal. In the present meta-analysis, there were insufficient data to conduct moderator analyses comparing African or South American samples with European or North American samples, and there were insufficient Asian samples to compare with European or North American samples on specific cognitive abilities. Although some non-WEIRD samples ($k = 8$; 4%) are included in the meta-analysis, the generalizability of the results is therefore somewhat limited.

Third, the reliability of the tests was not adequately documented in the included studies. In general, it is good scientific practice to report the psychometric properties of the instruments used. Yet, our study reveals that this is not routinely done for cognitive ability tests. When published, standardized tests are used true to manual reliability estimates can be derived from these manuals, but the manuals are usually not freely available. Moreover, the reliability of the samples studied may differ from that of the norming sample due to the characteristics of the sample itself (e.g., sample homogeneity). Even more problematic are studies that use only a subset of subtests and combine them into short scales that are not described in the manual or even combine self-developed tests and subtests of established tests. In these cases, there is little evidence on the reliability of the final test score. This unavailability of reliability estimates limits the interpretability of low stability estimates, as they may be due to actual rank-order changes in cognitive ability, low test reliability, or a combination of both.

Strengths and Limitations

The present meta-analysis has several strengths. It investigated a very broad set of studies published in the 100 years from 1921 to 2020, with mean baseline ages ranging from 1 to 88 years, test–retest

intervals ranging from 1 day to 79 years, and data collected in 29 countries and five continents. These data were the result of an extensive literature search based on two bibliographic databases and preexisting reviews on the subject matter. The statistical analyses represented the current state of the art and included wide-ranging moderator analyses involving theoretically relevant moderator variables. The analyses also included a detailed examination of the stability of the broad abilities in the CHC model and adjusting for test reliability in a subset of effect sizes.

The meta-analysis also has several limitations that need to be considered when interpreting the results. Where possible, specific measures were taken to minimize the consequences of these limitations.

The first limitation is that our age moderator analyses were based on the convergence assumption (Bell, 1953), assuming that differences in age between samples are informative about changes within the population. No one study investigated the stability of cognitive abilities from early childhood to late adulthood. Instead, we relied on the combination of information derived from across-sample age differences and from within-sample across-occasion stability to investigate age trends. This approach potentially confounds age differences, cohort differences, and methodological differences between studies, but this is only a major concern if these confounds are systematically associated with age (Tucker-Drob & Briley, 2014). Additionally, pertaining to the age moderator analyses, the utilized functional forms only represent a subset of possible mathematical functions that could be applied to approximate the empirical result patterns. Other functions, such as cubic or logarithmic functions, could have been applied additionally. Nevertheless, the utilized functions already covered all theoretically plausible trajectories, and the connected linear spline was included as a flexible function that could approximate result patterns that strongly deviated from the other functions.

The second limitation is that any minimum requirement used to accept or reject measures of cognitive abilities is necessarily somewhat arbitrary. Convincing arguments could be made for allowing the use of individual subtests or, conversely, for accepting only the use of complete tests. Our criteria were selected to allow the inclusion of a large and heterogeneous study base for different cognitive abilities while still maintaining a reasonable quality of the cognitive ability measurements. These criteria were preregistered. Moreover, we included a moderator analysis in which we compared the use of complete test batteries with the use of some form of subtest selection, thereby also applying a more conservative criterion.

The third limitation is that we did not investigate socioeconomic status (SES) as a moderator. SES could not be included because it was rarely reported, and the few available reports varied drastically in the operationalization of the construct (e.g., income, education level, International Socio-Economic Index of Occupational Status). This heterogeneity made it impossible to integrate the results. Previous findings suggest that the influence of genetic and environmental factors on cognitive abilities varies strongly with SES (Tucker-Drob & Bates, 2016; Turkheimer et al., 2003) and that both genetic and environmental factors contribute to the stability of cognitive abilities (Tucker-Drob & Briley, 2014). It is therefore quite plausible to assume that SES has some influence on stability. Future studies may address this research question systematically.

The fourth limitation is that we did not include the studies that reported latent correlations in the primary meta-analysis. Latent correlations are not directly comparable to manifest correlations because they are controlled for measurement error and therefore generally larger. To avoid losing the information contributed by these studies, we conducted a smaller, separate meta-analysis of latent stability estimates. The meta-analysis based on latent stability estimates generally indicated very similar stability to that indicated in our primary meta-analysis.

The fifth limitation is that most studies that investigate cognitive development in older adults exclude participants close to and beyond the clinical range of functioning. As a consequence, older adults are likely positively selected and also somewhat restricted in the range of included cognitive trajectories. Depending on sample age, this may constitute a substantial exclusion rate, with a prevalence of dementia of 17% in those aged 75–84 years and 32% in those aged 85 years or older in the United States (Hebert et al., 2013). This selection bias may limit the reordering in the older samples, as the individuals who contribute most to reordering are excluded. In turn, this may result in an overestimation of rank-order stability in this age range.

The sixth limitation is that our results and their implications may, in many respects, be restricted to the nonclinical population. We do not, for example, recommend the use of cognitive testing for long-term predictions in young children. However, many neurodevelopmental disorders are characterized, among other things, by specific cognitive deficits (Thapar et al., 2015) that can be detected early on and that remain throughout cognitive development. In these cases, cognitive testing may serve as a robust and valid aspect of diagnostic screening in early childhood, despite the low stability of cognitive abilities in the general population in this age range. These and other special cases of deviating stability in clinical subpopulations likely did not affect the results of this meta-analysis because of their rarity and because clinical samples were excluded from the analyses.

Conclusion

In summary, this meta-analysis of longitudinal studies showed that cognitive abilities exhibit high rank-order stability, reaching its peak around age 20 and remaining at this high level throughout adulthood and old age. The mean stability estimate for age 20 and the test–retest interval of 5 years were $\rho = .77$ for the observed correlations and $\rho = .86$ for the disattenuated correlations. Stability is much lower in young children. Before age 4, stability never exceeds .70, whereas in late adolescence, the stability no longer drops below this value for any test–retest interval. The low stability in young children cannot be explained by lower test reliability in this age group; overall, the correlation between test reliability and mean sample age is low. General intelligence and knowledge-based abilities were found to be somewhat more stable than abilities based on effortful processing ($\rho = .77$–$.80$ vs. $\rho = .65$–$.75$ for an age of 20 and an interval of 5 years). Reliability differences between tests of knowledge-based and effortful processing–based abilities in part account for the tests' differences in stability. Multidimensional intelligence tests may generally be preferred over unidimensional tests when the goal is a high stability of the test result, especially when there is no specific need for assessing individual ability domains. Our findings indicate that the use of cognitive testing in diagnostic decision making in younger children in particular may

require repetition over relatively short intervals of time, whereas retest intervals can be longer in adults. We have provided information on age-dependent maximum intervals (in years) for which a stability of .70 and .80 can be expected for cognitive ability measures.

Received November 4, 2022
Revision received December 7, 2023
Accepted December 7, 2023 ■

Deviations from the Pre-Registration

In the preregistration, we stated that 3,756 articles were screened for eligibility. Ultimately, however, 4,077 articles and chapters were screened, because search strategy 2 (PsycINFO search for books) was added during the revision process. This also explains the different number of excluded articles.

In the preregistration, we stated that we would control for the test-retest interval (and its nonlinear form, if necessary) in the analyses of H2. However, we decided to test H2 in three subsequent steps. In step 1, we only investigated the age effects without controlling for the test-retest interval effects. In step 2, age and test-retest interval effects were included simultaneously as registered. In step 3, the interaction of age and test-retest interval effects was also added. We deviated from preregistration to avoid convergence issues in the initial determination of the age effect in the first step. In steps 2 and 3, the test-retest interval was included in the analyses as preregistered.

Based on reviewer feedback, we added an analysis of a subset of stability effect sizes that were adjusted for their test reliabilities. This analysis was not preregistered and investigated differences in average stability and the age, test-retest-interval, and ability moderator analyses (H1-4) to the main dataset as an open research question. In the preregistration, we stated that studies reporting latent correlations would be included in the meta-analysis. However, as latent factors are measurement error-free, we decided it was more appropriate to include these studies in this exploratory analysis.

Test-Retest Interval and Age Interaction in Children and Adolescents

The analyses from H1 and H2 were repeated based on the subsample comprised of preschool children, school-aged children and adolescents to test possible interaction effects of

test-retest interval and age in this subpopulation. This was done to replicate the analyses conducted by Tucker-Drob and Briley (2014). Model fit indices for models testing linear, quadratic, and exponential test-retest interval and age effects and possible interaction effects are reported in Table S7. As in the complete dataset, the exponential functions reached the best model fits in for both moderators. However, in contrast to the complete dataset, the additional inclusion of the test-retest interval and age interaction did not lead to an improvement in model fit.

Results Based on Latent Correlations

Model fit indices for models testing linear, quadratic, and exponential test-retest interval and age effects and possible interaction effects based on latent correlations are reported in Table S8. Linear test-retest interval and age effects indicated the best fit. Step 2 and step 3 analyses indicated that the additional inclusion of the test-retest interval and age interaction did not lead to an improvement in model fit. The model parameters of the best fitting models are reported in Table S9. Note that the dataset based on latent correlations was too small for a meaningful interpretation of the parameters (i.e., $df < 4$).

The magnitude of rank order stability was ρ =.81 (df = 4.98, $p < .001$, CL [.68, .95]) when not controlling for test-retest interval and age (-20). Unfortunately, the dataset of latent correlations was too small to control for test-retest interval and age (-20). However, when residualizing out the effects of test-retest interval and age effects based on the results of the manifest correlations, a rank order stability of ρ = .85 (df = 4.93, $p < .001$, CL [.743, .951]) was observed for an expected test-retest interval of five years and a sample age of 20 years. Analyses testing H4 to H10 were not calculated because there were too few samples (i.e., h samples < 4).

Table S1

Information on Samples Providing Rank-Order Stability Effect Sizes Based on Manifest Values.

Note. Descriptive statistics are reported separately for manifest and latent correlations. All abils. = dataset including *g* and broad CHC abilities. t. = test. N. America = North America. S/C America = South America or Central America. Note that for the continuous variables *n* per study, *r*, duration of the test-retest intervals, age, and publication year we did not report the available *e* effect sizes and *h* samples, because there were no missing values on these variables.

Table S3

Correlations with Confidence Intervals of all Continuous Variables Based on the Complete Dataset.

Variable	1	2	3	4	5	6
***1. r* effect size**						
***2. n* per effect size**	.05 [-.01, .10]					
3. Duration of the test-retest intervals	-.22** [-.27, -.16]	.01 [-.05, .06]				
4. Age	.42** [.38, .47]	-.08** [-.14, -.03]	-.04 [-.09, .02]			
5. General cognitive ability level	-.07 [-.16, .02]	-.15** [-.23, -.05]	.09* [.00, .18]	-.05 [-.14, .05]		
6. Publication year	-.19** [-.24, -.14]	.11** [.06, .17]	.18** [.13, .23]	.13** [.07, .18]	-.09 [-.18, .01]	
7. α Reliability	.10 [-.02, .22]	-.14* [-.26, -.01]	.04 [-.09, .16]	-.18** [-.30, -.06]	.03 [-.22, .27]	-.09 [-.21, .03]

Note. Values in square brackets indicate the 95% confidence interval for each correlation. * indicates $p < .05$. ** indicates $p < .01$.

Table S5

Equations for the Meta-Regressions Testing Linear and Non-Linear Test-Retest Interval and Age Effects.

Meta-Regression Model	Equation	Description of Parameters
H1: Test-Retest Interval		
Linear interval model	$y_i = b_0 + b_1(\text{interval}_i)$	b_0 = *y* intercept b_1 = linear slope of interval
Quadratic interval model	$y_i = b_0 + b_1(\text{interval}_i) + b_2(\text{interval}_i^2)$	b_0 = *y* intercept b_1 = linear slope of interval b_2 = quadratic slope of interval
Exponential interval model	$y_i = b_0 - b_1 e^{b_2(\text{interval}_i)}$	b_0 = horizontal asymptote b_1 = interval scaling factor b_2 = interval growth rate
H2: Age		
Step 1. Age Without Additional Predictors		
Linear age model	$y_i = b_0 + b_1(\text{age}_i)$	b_0 = *y* intercept b_1 = linear slope of age
Quadratic age model	$y_i = b_0 + b_1(\text{age}_i) + b_2(\text{age}_i^2)$	b_0 = *y* intercept b_1 = linear slope of age b_2 = quadratic slope of age
Linear spline age model	$y_i = b_0 + b_1(\text{age}_{a,i}) + b_2(\text{age}_{b,i}) + b_3(\text{age}_{c,i}) + b_4(\text{age}_{d,i}) + b_5(\text{age}_{e,i})$	b_0 = *y* intercept b_1 = linear slope through age 6 b_2 = linear slope between age 6 and 18 b_3 = linear slope between age 18 and 65 b_4 = linear slope between age 65 and 80 b_5 = linear slope after age 80
Exponential age model	$y_i = b_0 - b_1 e^{b_2(\text{age}_i)}$	b_0 = horizontal asymptote b_1 = age scaling factor b_2 = age growth rate
Step 2. Test-Retest Interval and Age		
Linear interval + linear age model	$y_i = b_0 + b_1(\text{interval}_i) + b_2(\text{age}_i)$	b_0 = *y* intercept b_1 = linear slope of interval b_2 = linear slope of age
Linear interval + quadratic age model	$y_i = b_0 + b_1(\text{interval}_i) + b_2(\text{age}_i) + b_3(\text{age}_i^2)$	b_0 = *y* intercept b_1 = linear slope of interval b_2 = linear slope of age b_3 = quadratic slope of age

Supplemental Materials A

Meta-Regression Model	Equation	Description of Parameters
Linear interval + linear spline age model	$y_i = b_0 + b_1(\text{interval}_i) + b_2(\text{age}_{a,i}) + b_3(\text{age}_{b,i}) + b_4(\text{age}_{c,i}) + b_5(\text{age}_{a,i}) + b_6(\text{age}_{e,i})$	b_0 = *y* intercept b_1 = linear slope of interval b_2 = linear slope through age 6 b_3 = linear slope between age 6 and 18 b_4 = linear slope between age 18 and 65 b_5 = linear slope between age 65 and 80 b_6 = linear slope after age 80
Linear interval + exponential age model	$y_i = b_0 + b_1(\text{interval}_i) - b_2\, e^{b_3(\text{age}_i)}$	b_0 = *y* intercept of interval function b_1 = linear slope of interval b_2 = age scaling factor b_3 = age growth rate
Quadratic interval + linear age model	$y_i = b_0 + b_1(\text{interval}_i) + b_2(\text{interval}_i^2) + b_3(\text{age}_i)$	b_0 = *y* intercept b_1 = linear slope of interval b_2 = quadratic slope of interval b_3 = linear slope of age
Quadratic interval + quadratic age model	$y_i = b_0 + b_1(\text{interval}_i) + b_2(\text{interval}_i^2) + b_3(\text{age}_i) + b_4(\text{age}_i^2)$	b_0 = *y* intercept b_1 = linear slope of interval b_2 = quadratic slope of interval b_3 = linear slope of age b_4 = quadratic slope of age

Gwm	Intercept (b_0)	.713	4.625	< .001	[.644, .782]	86.247	.008
	Interval linear slope (b_1)	-.023	7.821	.110	[-.052, .006]		
	Age growth rate (b_2)	.037	9.570	.013	[.010, .064]		
	Age scaling factor (b_3)	-.122		.027			
	Interval-age-interaction (b_4)	-.002		< .001			

Note. Complete = Complete dataset including *g* and CHC broad abilities. As we subtracted 5 from the test-retest interval, the intercepts in models including test-retest interval represented a 5-year interval instead of a 0-year interval. As we subtracted 20 from the age, the intercepts in models including age represented a 20-year age instead of a 0-year age. Because of this, the intercepts in models including five linear spline predictors represents a 20-year age instead (because 20 years were added to the intercept for each linear spline predictor).

Table S7

Model Fit Indices of Models Testing Linear and Non-Linear Test-Retest Interval and Age Effects in a Subsample of Children and Adolescents.

Dataset	Model	LL	SCF	AIC	BIC
H1: Test-retest interval

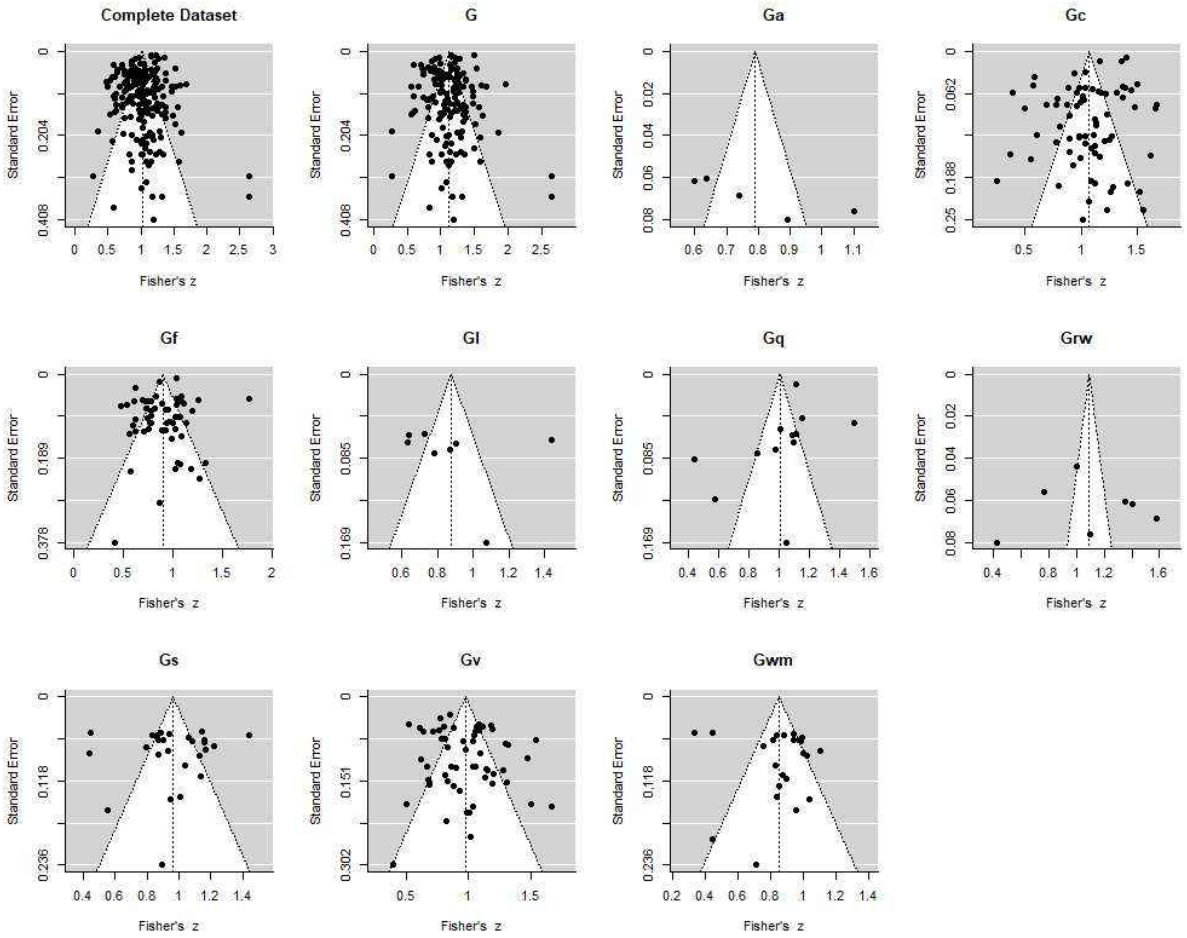
Gl	Intercept	.688	6.990	< .001	[.591, .786]	95.529	.025
Gq	Intercept	.770	10.005	< .001	[.711, .829]	93.647	.004
Grw	Intercept	.776	5.897	< .001	[.636, .915]	96.280	.008
Gs	Intercept	.738	24.129	< .001	[.695, .781]	91.977	.008
Gv	Intercept	.747	55.570	< .001	[.719, .775]	90.031	.009
Gwm	Intercept	.688	20.835	< .001	[.638, .739]	87.102	.009
Robustness Check 3. Magnitude of ρ After Deleting Effect Sizes Causing Asymmetry							
Complete	Intercept	.764	186.77	< .001	[.750, .778]	95.056	.006
G	Intercept	.801	135.81	< .001	[.787, .816]	96.343	.006

Note. Robustness check 1 was conducted based on effect sizes that were not residualized by *test-retest* and *age* effects. Robustness check 2 was conducted after influential outlier effect sizes were deleted from the datasets. Complete = Complete dataset including G and all Stratum II abilities.

Figure S1

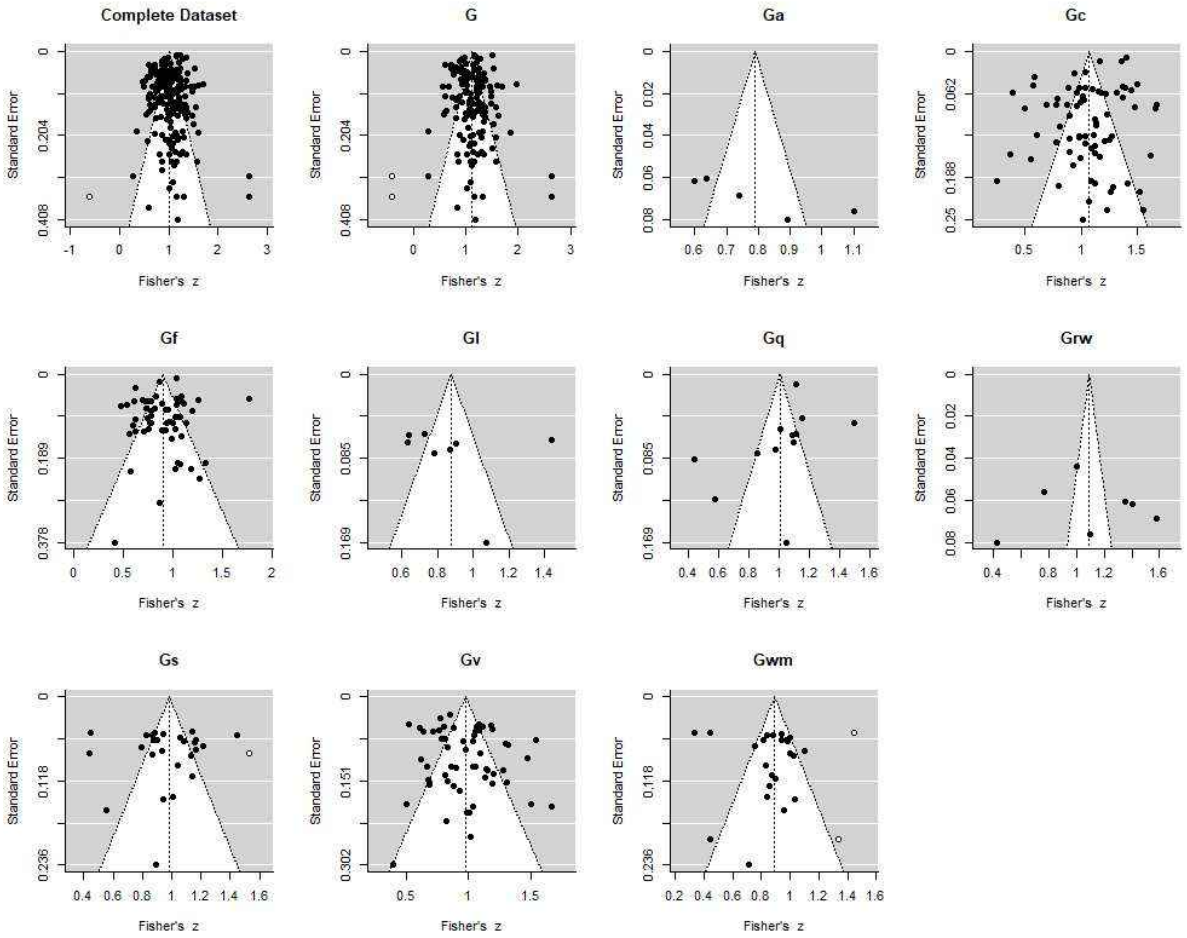
Funnel Plots Based on Fishers' z Effect Sizes.



Notes. Funnel plots were conducted based on aggregated effect sizes from same studies. Prior to the analyses, test-retest and age effects were residualized out.

Figure S2

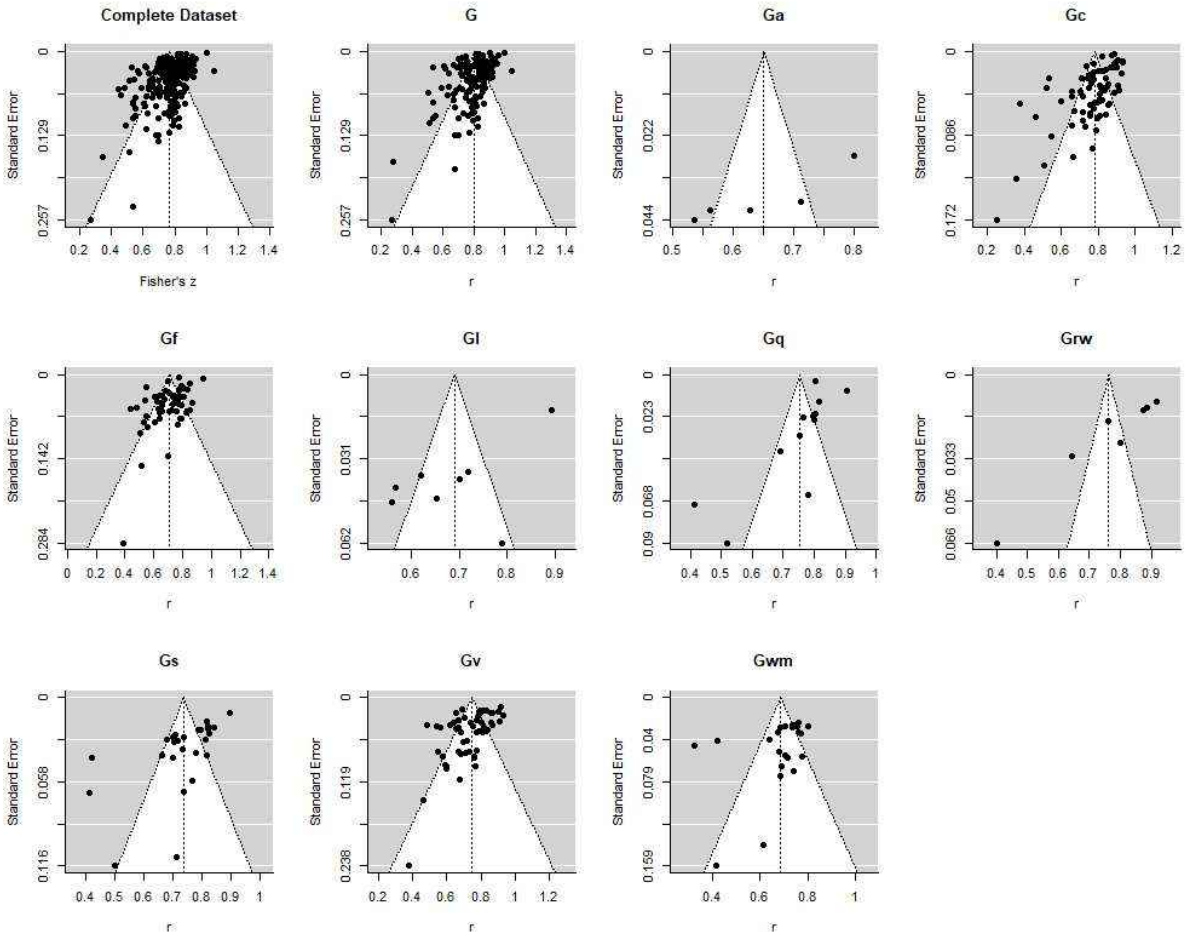
Trim-and-Fill Plots Based on Fishers' z Effect Sizes.



Notes. Funnel plots were conducted based on aggregated effect sizes from same studies. Prior to the analyses, test-retest and age effects were residualized out.

Figure S3

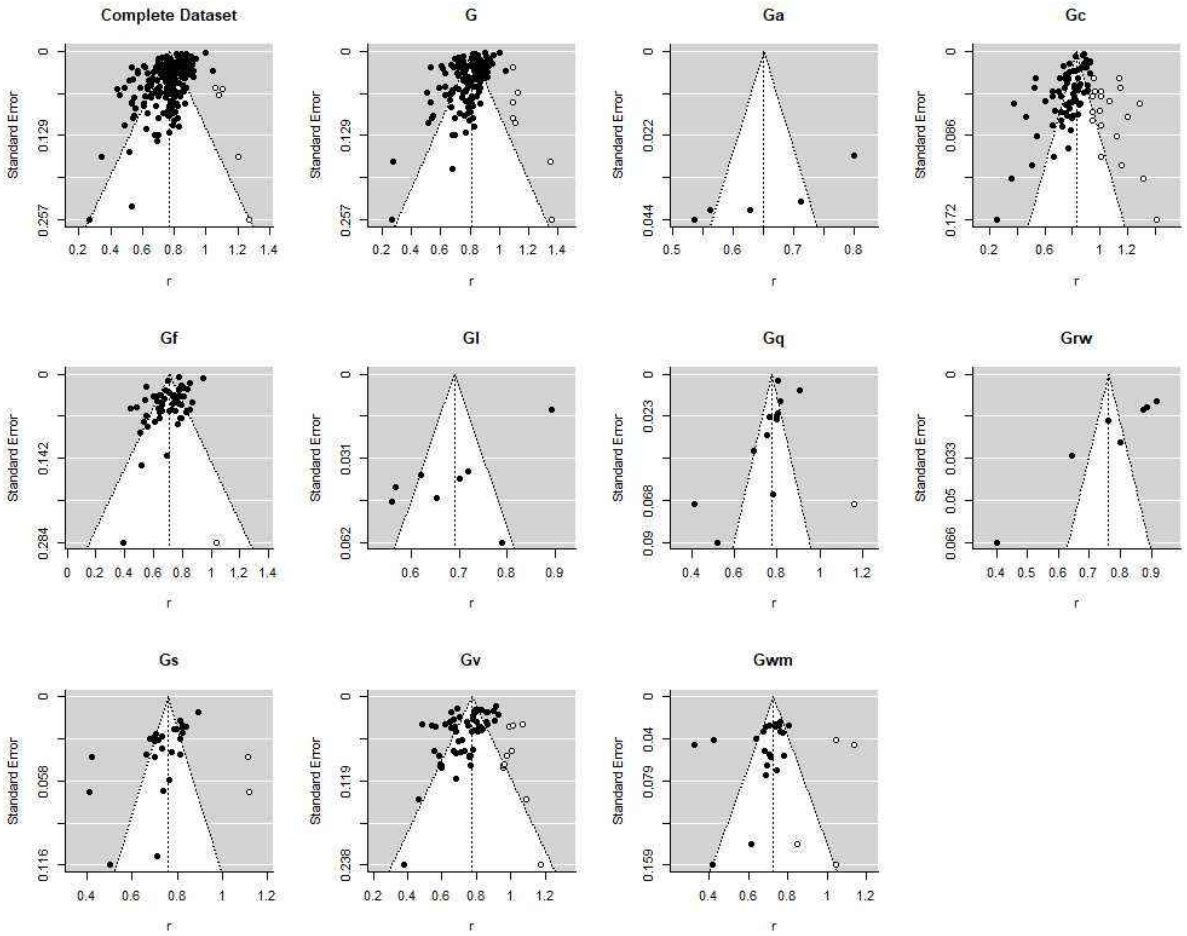
Funnel Plots Based on r Effect Sizes



Notes. Funnel plots were conducted based on aggregated effect sizes from the same studies. Prior to the analyses, test-retest and age effects were residualized out.

Figure S4

Trim-and-Fill Plots Based on r Effect Sizes.



Notes. Trim-and-fill plots were conducted based on aggregated effect sizes from the same studies. Prior to the analyses, test-retest and age effects were residualized out.

Figure S5

Best Fitting Test-Retest Interval Duration Moderation Curves for all Abilities.

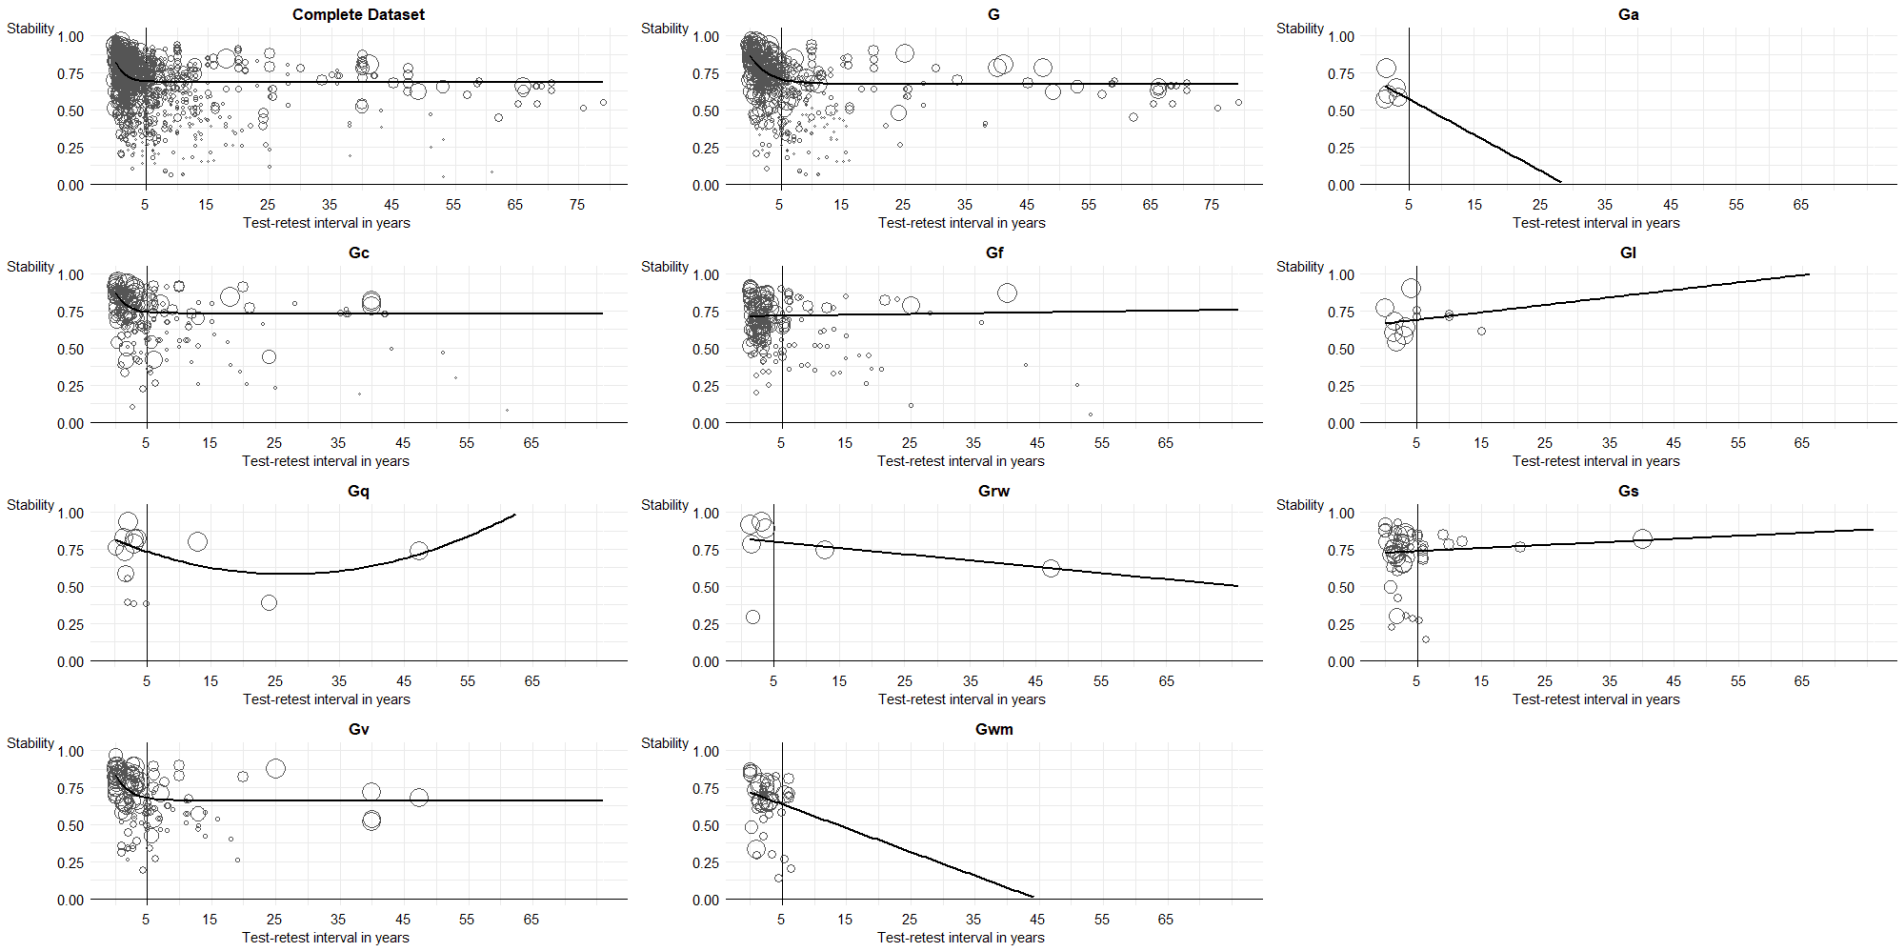


Figure S6

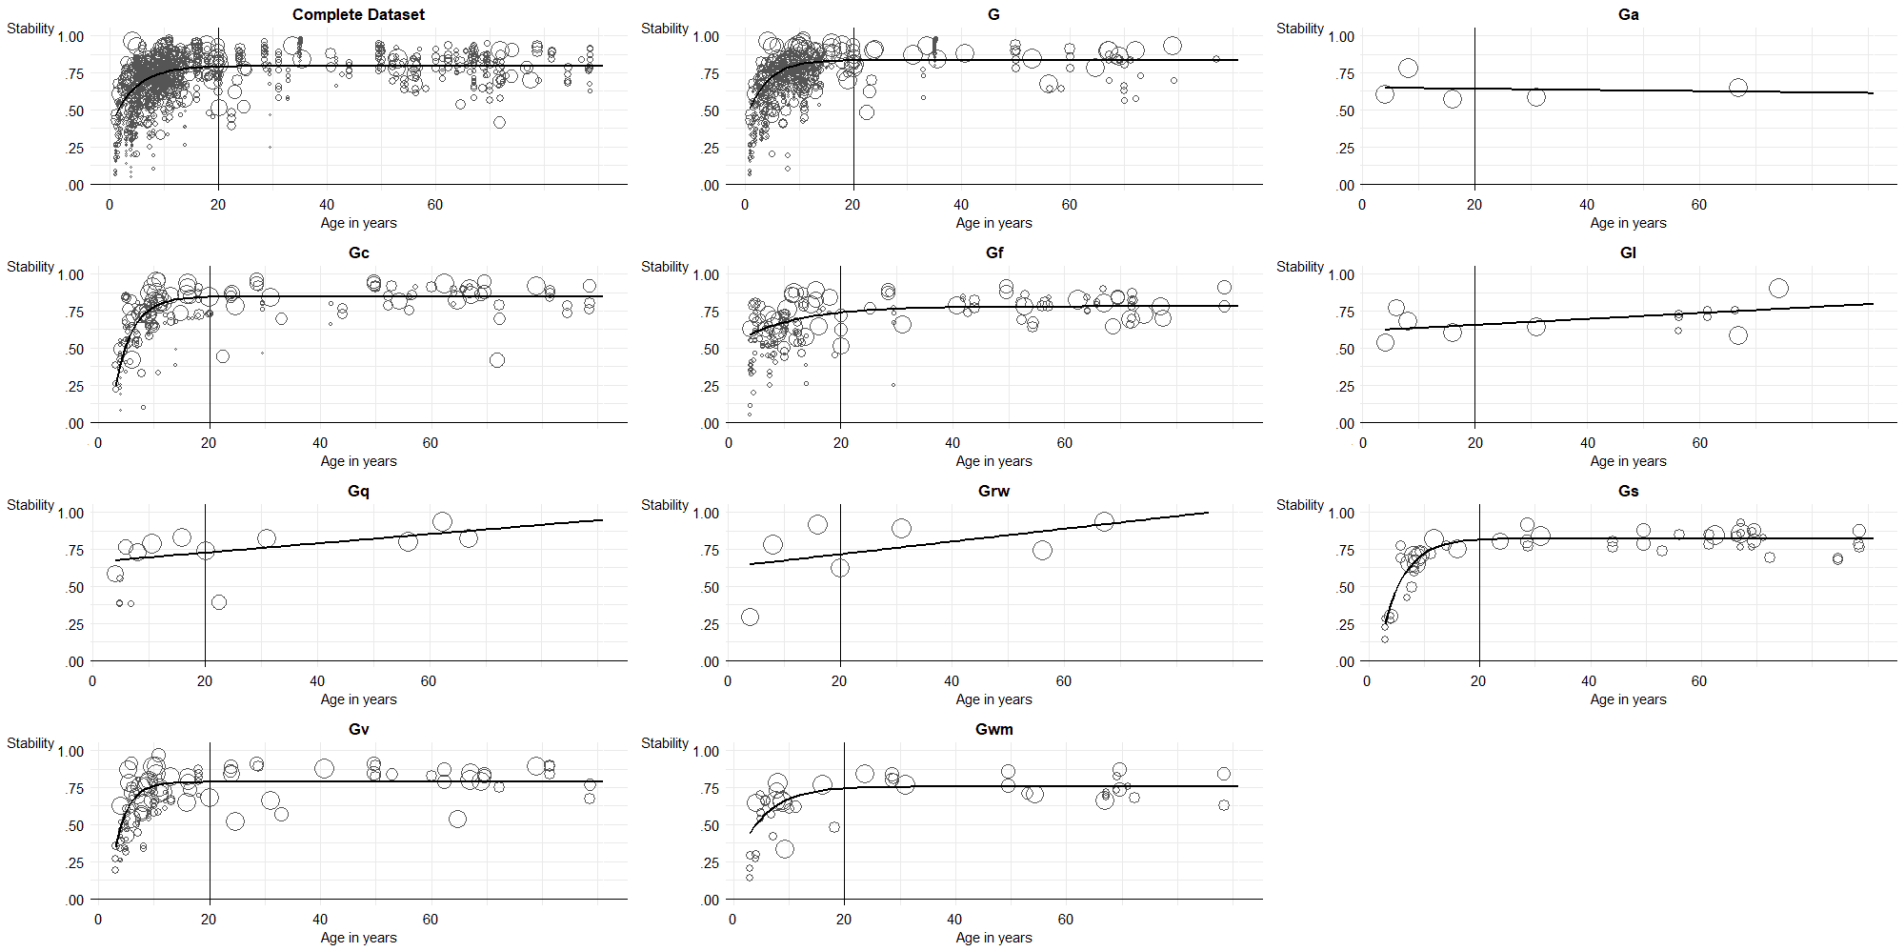
Best Fitting Age Moderation Curves for all Abilities.



List of Studies Included in the Meta-Analysis

*Adkins, D. C. (1937). The efficiency of certain intelligence tests in predicting scholarship scores. *Journal of Educational Psychology*, *28*(2), 129–134. https://doi.org/10.1037/h0058951

*Allan, M. E., & Young, F. M. (1943). The constancy of the intelligence quotient as indicated by retests of 130 children. *Journal of Applied Psychology*, *27*(1), 41–60. https://doi.org/10.1037/h0054264

*Allen, M. M. (1945). Relationship between the indices of intelligence derived from the Kuhlmann-Anderson intelligence tests for grade I and the same tests for grade IV. *Journal of Educational Psychology*, *36*(4), 252–256. https://doi.org/10.1037/h0058184

*Almas, A. N., Degnan, K. A., Nelson, C. A., Zeanah, C. H., & Fox, N. A. (2016). Iq at age 12 following a history of institutional care: Findings from the Bucharest Early Intervention Project. *Developmental Psychology*, *52*(11), 1858–1866. https://doi.org/10.1037/dev0000167

*Arthur Jr, W., Glaze, R. M., Villado, A. J., & Taylor, J. E. (2010). The magnitude and extent of cheating and response distortion effects on unproctored internet-based tests of cognitive ability and personality. *International Journal of Selection and Assessment*, *18*(1), 1–16. https://doi.org/10.1111/j.1468-2389.2010.00476.x
